The health statistics of the Berar jails for 1884 compare favourably with the previous year, and "bear testimony," it is stated, "that the physical condition of the "prisoners is sufficiently attended to. They are further confirmed by the fact that "of the prisoners discharged during the year no less than 70 per cent. gained weight "during the period of their incarceration." The average daily sick-rate was remarkably low (11 per 1,000), and the general death-rate was only 8·72, identically the same as in 1883. There are six jails in the province, but the only two of any considerable size are the central jails of Amraoti and Akola. All the jails were free from death but Akola, where there were 9 deaths, equal to 20·2 per 1,000 of strength. The Inspector-General reports favourably of the general administration of the jails, and states that there was no overcrowding for any length of time in any of them.

Assam.

Sickness was more prevalent in the jails of Assam during 1884 than in any of the four years preceding, and there was a marked increase in mortality. Among all classes of prisoners the deaths were in the ratio of 61·19 per 1,000 of average strength against 43·12 in 1883. This excess was mainly due to an increased mortality from bowel complaints, respiratory diseases, and fevers. Cholera also was very prevalent, and caused 10 deaths, or 6·93, of the total mortality. The only jail in the province of any considerable size is Sylhet, with an average daily strength in 1884 of 517. Here the admission-rate (2,350) was very high, as was also the death-rate (70·8). Among convicts the admissions to hospital continued steadily to increase. Of an average daily strength of 1,328 of this class of prisoners the admission-rate was 2,300 per 1,000 against 2,102 in 1883, the daily average sick-rate 66 per 1,000 against 51, and the death rate 60·25 against 43·22. It is difficult to assign any cause for this increased mortality; it is stated "there were only 9 fatal cases of cholera (though "the disease was generally prevalent in the province), the same as in 1883. There "is nothing to show that the past year was a particularly unhealthy one; the only "conclusion, therefore, that the Officiating Chief Commissioner can come to is that "much of the mortality is due to accident."

British Burma.

The health of the jail population of British Burma in 1884 was not, on the whole, so good as in the previous year. The ratio of admissions to hospital was less, namely, 936 against 1,159 per 1,000, but the death-rate rose from 28·94 to 30·28. The total number of deaths in 1884 was 202 against 155 in 1883, the increase being mainly due to a larger number of deaths from anæmia and debility, small-pox, and bowel

complaints. There were in all 50 admissions from small-pox with 13 deaths, against two admissions and no deaths in the previous year. Of these 13 deaths 9 occurred among the convicts at Rangoon and 3 at Moulmein, the disease having been very prevalent during the year at both places. Cholera yielded 44 cases, of which 32 proved fatal, against 42 fatal cases in 1883; and it was present in five out of the 14 jails of the province. Two-thirds of the cholera deaths (22) occurred among the prisoners in the Akyab jail, or in the proportion of 52·76 per 1,000 of its average strength. This was the only serious epidemic, and the removal of half the prisoners to temporary quarters stopped it. As usual, the death-rate from all causes was highest among convicts recently admitted, and lowest among those who had been more than seven years in jail. An experiment was tried during the year of substituting pulse for fish in the rations of native prisoners two or three times a week, and so far as could be ascertained the change was attended with satisfactory results.

V.—VACCINATION.

General results.

The vaccination returns for the whole of India show a marked improvement on the previous year, though a large number of the population still remained unprotected. At the special vaccination establishments and dispensaries 4,770,118 successful vaccinations were performed among an estimated population of about 184 millions. Of these, 1,828,059 were children under one year of age, or less than a fourth of the estimated births. "This," the Army Sanitary Commission state, "is the only safe way of testing "the probable effect of vaccination, for whatever the number of vaccinations above one "year may amount to we have added year by year some millions of infants who are "the most susceptible subjects to attacks of small-pox, only one-fourth of the number "being protected."

Bengal.

Considerable progress was made in vaccination work in Bengal during 1884–85. With an increase of 147 officers to the staff the number of vaccinations rose from 1,364,642 in the previous year to 1,488,296, being an increase of 123,654. To this improvement all the circles, excepting Orissa and the municipal area, contributed. Of the total number of vaccinations, Government and licensed vaccinators performed 1,402,260, the rest by vaccinators attached to municipalities, dispensaries, &c. The increase, however, was entirely in primary cases, for secondary operations fell from 13,198 to 12,794; and of the 1,475,502 primary cases 99·38 per cent. were successful against a corresponding per-centage of 98·66 in 1883–84. By age children between one and six years of age were, as usual, the most largely protected, being at the rate of 66·74 per cent. of the total primary vaccinations; but the fact that the great majority of the small-pox deaths occurred among infants and children shows that much still remains to be done in protecting them by vaccination. Estimating the births within the vaccination area at 30 per 1,000 of population gives a total of 1,517,149, and out of this number only 211,480, or nearly 14 per cent., were protected. "The practical "result hence appears to be," the Army Sanitary Commission observe, "that, although "the total vaccinations do not fall very much short of the births within the vaccinated "area, they are so distributed among the ages as to afford little protection to the infant "population. This defect points to the necessity of an improved direction of the "work towards the ages under one year." Bovine lymph was largely used during the year, and, on the whole, was attended with satisfactory results. The Compulsory Vaccination Act was extended in the course of the year to several new police circles and towns, and the law is now in force in 81 towns, four cantonments, and nine rural areas; steps have also been taken to extend it to other municipalities.

The year's results also show a general improvement in inspection work, which was attributed to the close check kept over the proceedings of the different officers month after month during the year. Altogether 33,413 villages were inspected, and out of 1,397,500 vaccinations 1,124,377, being 191,182 above the number of the previous year, were examined. Of these 1,089,417 cases were found to have been successful.

As regards the attitude of the people towards vaccination, the Sanitary Commissioner says: "There is evidence in the Reports of the officers of the Vaccination "Department that vaccination is appreciated in many places, and that the ignorant "prejudices, mistrust, and opposition of former years are gradually giving way to a "healthier view of vaccination." And the Lieutenant-Governor in his Resolution on the Sanitary Commissioner's Report says: "Experience of the beneficial effects of "vaccination is slowly, but surely, popularizing it wherever it is introduced: it is a "work of time, and inoculation is still a powerful rival; but every year shows that "the superiority of vaccination is more generally acknowledged."

Madras.

Good progress was made in vaccination work in the Madras Presidency during 1884. The total number of operations performed was 803,469, or 49,880 more than in 1883; of these 773,118 were primary vaccinations with a ratio of success of 92·6 per cent. By far the largest number of cases were children between one and six years of age, namely, 375,687; while of infants under one year of age only 135,916 were successfully vaccinated, but this was an increase of 4,545 on the number of the previous year. Still the fact that only 19·5 per cent. of the surviving children born during 1884 were protected from small-pox shows how much remains to be done. "The remedy suggested by the year's experience is," the Army Sanitary Commission remark, "that the Madras "vaccination service should be directed to overtaking the births at ages under one

" year. But the great predisposition to small-pox epidemics in Madras Presidency " must be met by strenuous endeavours to improve the sanitary condition of the " population." Owing to the great prevalence of small-pox in Madras town vaccination was made compulsory there from the 23rd May 1884; and in order to give the people the necessary facilities for complying with the terms of the Act eight vaccine depôts were opened in various parts of the town, where the operations were performed. As regards the attitude of the people towards vaccination the Inspector of Vaccination in his Report for 1844 says: "There is still in some parts of the " Presidency a feeling against vaccination, although not so strong as it was. In some " parts a healthier view of vaccination is gaining ground, and people willingly come " forward to be vaccinated, especially when small-pox prevails. The cause of " vaccination has also progressed in places where the officials take personal interest in " pushing it on."

Bombay.

During 1884–85 there were 865,568 persons vaccinated in the Bombay Presidency, being a decrease of 18,271 on the number of the previous year. Primary operations numbered 802,207 against 826,965, and of these 764,445, or 95·29 per cent., were successful, being 0·40 per cent. below 1883–84. In the protection of infants the year's returns show a satisfactory improvement, 63·41 per cent. of the total number of infants under one year of age (reckoning the births at 31 per 1,000 of the population), having been successfully vaccinated as compared with 61 per cent. in the previous year. Except in Bombay City, where animal lymph only is used, and a few other places where both animal and human lymph were in use, vaccination in all other places was carried on with human lymph. In the work of inspection the vaccination staff made 4,546 encampments, travelled 87,076 miles in 8,063 days, and inspected 832,759 children in 12,709 villages; but only 38·44 per cent. of the total operations were inspected against 40·76 in the previous year.

The Compulsory Vaccination Acts in Bombay City and Karachi continue to work satisfactorily, and in both cities considerable progress was made in the protection of infants.

Punjab.

Owing to the excessive prevalence of fevers among the infantile population during the autumn months the vaccination returns for the Punjab for 1884–85 do not compare favourably with those of the previous year. The total operations numbered 583,498 against 633,062 in 1883–84, of which 567,711 and 624,873 respectively were primary cases. Of the primary vaccinations 94·78 per cent. were successful, a trifle better than in 1883–84. The number of infants successfully vaccinated was 406,858, little more than half of the 809,912 registered births of the year; and 92 per cent. of the primary vaccinations were among children under six years of age. In discussing the vaccination work of the year the Army Sanitary Commission notice that during the preceding five years the ratios of vaccinations to deaths were 20·30 and 1·14 per 1,000 respectively. And they say: "If the population continued to live for the next half century without " any addition by births, it would be by that time protected, and this merely shows " how inadequate the work done is to the emergency. We are glad to know that of " recent years the service has been greatly improved, and that the annual mortality " table already given (Appendix, p. 194) appears to show that good results have been " already attained. But the practical result of all the past experience appears to be " that, while the tendency of the disease to take on the epidemic character must be " met by improving the sanitary condition of the people and of the localities they " inhabit, the vaccination work must be more specially directed to protecting infantile " ages, when most good may be done in the way of warding off attacks of the disease " in after life."

North-Western Provinces and Oudh.

The vaccination returns for the North-Western Provinces and Oudh for 1884 show that 656,561 vaccinations were performed during the year, being an increase of 7,494 on 1883. The successful primary vaccinations, however, were not so numerous, numbering 563,864, or 87·94 per cent. of the total primary cases, against 565,351, or 92·10. Of the successful cases only 294,583 were under one year of age, being in the proportion of about 15 per cent. of the registered births. This diminution of successful operations was attributed to three causes: the prevalence of fever and small-pox, the supply of an inferior quality of lymph, and a want of energy on the part of the establishments, especially in Oudh, consequent on the introduction of the rule which retains them throughout the year in the districts in which they are employed. Steps were being taken for remedying this last cause, and the Government of India hoped that they would be carried out without loss of time.

In discussing the value of vaccination the Army Sanitary Commission point out that "in ordinary years lives are no doubt saved, and lower small-pox death-rates may be "co-existent with numerous operations. But this and similar experience appears to "show that the remedies, if such be available, will have to be extended beyond "vaccination, and will have to deal with epidemic causes, affecting localities and their "inhabitants. If sanitary work be neglected, no more dependence against small-pox "epidemics can be placed on vaccination than can be placed on quarantine against "invasions of cholera. The true remedies lie elsewhere altogether."

Central Provinces.

The returns of vaccination in the Central Provinces for 1884–85 show an increase in operations over the previous year of 5,683, the total number being 415,804 against 410,121 in 1883–84. Of these 400,455 were primary operations with a per-centage of success of 96·30, which is less by 0·89 than in the previous year. According to age 183,740 of the successful cases were infants under one year, being in the proportion of nearly 50 per cent. of the registered births, and 175,545 were children between one and under six years of age. The proportion of persons protected by vaccination during the year equalled about 38·27 per 1,000 of the population of the province. The work of inspection appears to have been creditably performed during the year, and it is satisfactory to learn that the attitude of the people has improved. Nowhere are the people hostile, though they are generally indifferent; but the people are reported to be not infrequently favourable to vaccination, and acknowledge the cordial and valuable assistance given by some of the vaccination staff. "There is little doubt," the Chief Commissioner observes, "that any difficulty still experienced may easily be overcome "by tact and patience."

Berar.

The statistics of vaccination in Berar for 1884–85 testify to continued improvement. The total number of operations performed by all establishments was 101,134, or 14,413 in excess of the number of the previous year. Almost all the year's work consisted of primary vaccinations, which numbered 100,970, and of these 95,895, or 94·9 per cent., were returned as successful against a per-centage of 92·6 in 1883–84. Of the total operations 93,517 were performed by the Vaccination Department, all but 82 being primary cases, and the per-centage of success was in the proportion of 95·3 against 92·9 in 1883–84. According to age the largest number of operations was performed upon infants, no less than 72·9 per cent. being children under one year of age. The per-centage of infants successfully vaccinated to estimated births at the rate of 40 per 1,000 of population rose from 53 in 1883–84 to 66·6, which was made up of ratios in the six districts ranging from 59·0 in Basim to 84·4 in Ellichpur. Considerable progress was also made in the work of supervision during the year, as 70 per cent. of the villages in which work was carried on and 56·2 per cent. of the total number of vaccinations were inspected by the superintendents. The per-centage of the season's work verified was highest in the Ellichpur district, where it reached 80·2, and lowest in Buldana, where only 41·1 per cent. of the total work was verified. "On the whole," the Superintendent of Vaccination, Dr. Little, states, "the work performed during "the year by all establishments was satisfactory; the conduct of the vaccinators "towards the people was, as a rule, kind and conciliatory, and complaints against "them were few. There was little opposition, except amongst certain castes, and "this is gradually diminishing."

Assam.

The results of vaccination in Assam for 1884–85 were satisfactory, showing a general advance and improvement. The total number of operations rose from 88,693 in 1883–84 to 103,731, showing an increase in 1884–85 of 15,038, which was spread over the entire province except in Sylhet and Cachar, where there was a falling off of 4,345 and 316 cases respectively. In the work done by tea agency there was also a decrease of 1,887 operations. Of the total vaccinations of the year 103,148 were primary cases, and of these 92,400, or 89·58 per cent. against 86·66 in 1883–84, were successful. There was, however, a marked difference in the work done by Government agency and that done by medical officers of tea gardens, that of the former having been attended with a success per-centage of 91·2 against 91·36 in 1883–84, and that of the latter of only 64·9. As previously stated the province on the whole during the year was remarkably exempt from small-pox, and there were indications that vaccination was repelling the disease in localities where the former had been systematically worked and its genuine protection adequately superintended. At the date of the Sanitary Commissioner's report small-pox was severely epidemic in the Khasi Hills, "and these foolish people," that officer states, "who last year threatened to disturb

" the public peace if the inoculators were prohibited, are now crying aloud for vacci-
" nation instead, and admit they have been led into their present trouble." The results of the year also show a satisfactory improvement in inspection work, the number of cases inspected having risen from 25,092, or 32 per cent. of the total operations in the previous year, to 42,534, or 41 per cent.

Throughout 1884–85 vaccination was carried on with greater success in British Burma than in the previous year, and several medical officers are reported to have taken a personal interest in, and to have worked hard for, the cause. The total number of persons vaccinated, including 744 dispensary cases, was 90,667, of which 83,518 were primary operations. The total operations performed by the vaccination staff were 89,923, a greater number than in the previous year by 16,654, which was accounted for by a new district (Salween) being for the first time brought under operation, and by a great increase in several other districts. The primary cases numbered 82,805 with a per-centage of success of 84·36, which was somewhat less than in 1883–84; but the average number of operations performed by each vaccinator was greater. The Sanitary Commissioner calculates that not more than one-tenth of the children born during the year were successfully vaccinated; " it is evident, therefore," as the Chief Commissioner remarks, " that there is still room for a very great extension of vaccination " operations." The Compulsory Vaccination Act was at the request of the Municipal Committees introduced into Rangoon and Akyab. British Burma.

VI.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

Bengal.

There were 230 dispensaries at work in Bengal during 1884, of which five were chiefly supported by the State, 86 supported by local funds, 81 maintained at the cost of private individuals or associations, and 58 maintained by private subscriptions or guarantee, but receiving aid from Government or local funds. The total number of patients under treatment was 390,632, or 52,411 over the previous year. The Inspector-General attributed this increase mainly to greater care in recording entries, in consequence of more attentive inspections. "In the towns and villages," he says, "where "independent medical men have set up in private practice, we no longer look for the "attendance at our dispensaries of those who can afford to pay for medical advice and "medicines. In some situations the falling off of patients at our public charities "and the slow growth of attendance at others, are no criterion that there is any real "diminution in the benefits conferred on the sick poor, or that the European systems "of medicine and surgery are held in less esteem by the people; but may, with every "reason, be received as evidence of the fact that, whereas formerly, the better classes, "having no alternative, sought relief during illness at our public hospitals, now "engage for themselves and families the services of private practitioners. Independent medical men have established themselves in practice throughout the country; "and while many are succeeding well, the majority may be said to be gaining a fair "and honourable livelihood by the exercise of their profession." Of the total number of patients, 25,077 were in-door patients, being more by 2,609 than in 1883. The number of this class of patients cured was 13,183, while 3,813 were relieved, 3,173 were otherwise discharged, and 3,701 died, the death-rate to total treated being 147·5 per 1,000 against 141·3 in 1883.

The health of the town of Calcutta during 1884 was very unfavourable, cholera and small-pox having prevailed with more than usual severity. At the six Calcutta hospitals the in-door patients increased from 20,381 in 1883 to 21,360; but, on the other hand, the out-door patients treated decreased from 239,337 to 235,685, which was attributed to "the establishment of chemists' shops throughout the town, to "which qualified surgeons are attached, who give advice and perform minor operations "free of charge."

The following table shows the number of patients under treatment in the several hospitals in Calcutta during 1884 and the previous year, and the mortality which occurred among the in-door patients:—

Medical Institutions.	1884.				1883.			
	Total Treated.			Died per 1,000 of treated.	Total Treated.			Died per 1,000 of treated.
	In-door.	Out-door.	Total.		In-door.	Out-door.	Total.	
Medical College Hospital	9,522	44,062	53,084	126·1*	8,597	51,022	59,619	112·08*
Presidency General Hospital	3,073	—	3,073	40·38	3,121	—	3,121	47·7
Mayo Hospital and Dispensary	2,461	181,274	183,735	159·63	2,319	176,219	178,531	144·5
Campbell Hospital	6,525	—	6,525	236·01	5,469	—	5,469	224·04
Police Hospital	2,221	—	2,221	19·8	2,375	—	2,375	11·7
Total Calcutta Hospitals	19,792	225,336	245,628	149·6	18,730	227,241	245,391	131·13
Howrah General Hospital	1,568	9,849	11,417	223·57	1,651	11,986	13,637	200·4
Grand Total	21,360	235,685	257,045	146·7	20,381	239,337	259,718	139·85

* Reckoned on the cases treated, exclusive of ophthalmic cases.

It will be seen from the above table that the death-rate was in excess of that of 1883 by nearly 10 per 1,000, the number of deaths having risen from 2,719 to 3,058. Of these, 536 were due to cholera and 86 to small-pox, against 510 and 35 respectively in 1883; but, exclusive of these two diseases, the year's returns showed an increase of 262 deaths, or 9·23 per cent. Dysentery also furnished a large mortality, but from all three diseases the per-centage of deaths to cases treated showed a decrease in severity. Chest diseases yielded a heavy mortality, and there is reason to believe, it is stated, "that a vitiated state of the air breathed was the principal cause rather than changes "in temperature." The number of important surgical operations performed during the year was 1,368, or 115 more than in 1883. Of these, cures were effected in 910 cases, in 139 relief was afforded, and death resulted in 99 cases. In minor

operations, numbering 18,737, there was an increase of 2,864 as compared with the previous year.

The system of nursing established at the Medical College and general hospitals under the superintendence of the ladies of the Clewer Sisterhood was reported on in the highest terms, and the Lieutenant-Governor of Bengal again recorded his recognition and high appreciation of the good work done by them.

Madras.

In the Madras Presidency the number of civil hospitals and dispensaries increased from 287 in 1883 to 299 in 1884, of which 87 were in charge of civil apothecaries. The eleemosynary education for the grade of civil apothecary was discontinued from 1st January 1885, and after June 1888 local bodies will have to find their own medical subordinates. The number of patients treated during the year was 1,753,898, against 1,696,809 in 1883, the increase, as usual, occurring chiefly among out-patients. There were 39,826 in-patients, or 1,379 more than in the previous year, of whom 3,100, or 77·8 per 1,000, died. This mortality was greater by 2·3 per 1,000 than that of 1883, and was chiefly attributable to the prevalence of cholera, which, as already stated, committed considerable ravages in the southern districts of Madras. The total cholera cases under treatment during the year at these institutions numbered 14,558, and the deaths 5,735. Of these, 748 cases and 425 deaths occurred among the in-patients, being in the ratio of 10·6 per 1,000 of their total strength. The year's work also witnesses to an increase in surgical operations from 49,180 in 1880 to 53,247. Major operations numbered 3,358, or 96 more than in the previous year, and of these 2,684 resulted in cure.

Bombay.

The total number of hospitals and dispensaries at work in the Bombay Presidency during 1884 was 208, or six more than in the previous year. Of these, 47 were maintained by provincial funds, 33 by local and municipal funds, 25 at the cost of private individuals or associations, while the rest were supported by private subscriptions, supplemented by grants from provincial or local funds. The number of patients treated rose from 1,372,249 in 1883 to 1,491,170, which was attributed partly to the increase in the number of institutions and partly to their extended popularity, for, as previously stated, the year 1884 in this Presidency was comparatively a healthy one. The increase of patients, however, was chiefly among the out-door class, for the in-patients increased only from 36,255 in 1883 to 36,402. Of these, 25,740 were cured, 3,611 were relieved, 3,565 were otherwise discharged, and 2,553 died, the ratio per 1,000 of deaths to total treated being 70, the same as in 1883. Malarious fever was, as usual, the disease by which far the largest number of patients (274,762) was treated. This disease was very prevalent during the year, and was no doubt partly answerable, it is stated, to the increase in the number of patients. Cholera cases fell from 6,215 in 1883 to 1,943, while small-pox cases rose from 845 to 1,099. The number of persons treated for venereal diseases of all kinds was 33,181, or 110 more than in the previous year. Major operations to the number of 4,182 were performed during 1884, of which 3,651 were discharged as cured, and 172 died. Minor operations numbered 76,546, being an increase of 1,124 on 1883. The minor operations, the Surgeon-General states, "continue to increase year by year, and "although individually they are of little importance, yet collectively they represent "the relief, temporary or permanent, from much physical suffering."

Punjab.

Six new dispensaries were opened in the Punjab during 1884 and one branch dispensary at Peshawar was closed, leaving 196 in operation; these included one State hospital, 194 dispensaries guaranteed or maintained by local funds, and one maintained partly at the cost of private individuals. The total number of patients treated was 1,781,939, showing the large increase of 183,683 over the previous year, which was partly due to the opening of new dispensaries, but mainly to the great unhealthiness of the year. In-door patients numbered 39,300, being an increase of 1,284 on the number for 1883, and among them there were 1,938 deaths, or 49·3 per 1,000, against 2,041 or 53·7. The principal diseases under treatment were malarial fevers, ophthalmia, respiratory affections, and ulcers. The first of these shows an increase of 99,770 cases (369,024 against 269,254) over the previous year, and ophthalmia an increase of 17,100. The number of persons seeking treatment for this latter disease is steadily increasing year by year. In 1881 the cases numbered 90,820 and in 1884 they had reached 132,307. No cause for this increase has yet been definitely assigned, but it is probable, it is reported, that the growing popularity of the dispensaries has something to do with the increased number of cases treated. Respiratory affections

rose from 128,954 in 1883 to 137,222. Cases of small-pox also increased from 245 to 366, while cholera cases declined from 113 to 94. The number of major operations performed in the course of the year amounted to 8,313, exceeding the number of 1883 by 1,667. In obstetric cases there was an increase of 139 on the figures of 1883 (893 against 254). It appears that steps were being taken "to effect the substitution of "trained nurses for the present ignorant and inefficient dhai, whose malpractices are "the cause of considerable loss of infant life and protracted suffering, and not "infrequently death to the mother." It is reported that in some places there was an overcrowding of in-patients, especially at Delhi, where the inadequacy of the existing hospital had long been felt. Steps were being taken towards providing the city with a more suitable hospital; subscriptions amounting to about Rs. 70,000 were collected, Government had promised a grant-in-aid of Rs. 10,000, and Rs. 50,000 had been promised from municipal and district funds, and it was anticipated that other assets would bring the total building fund to about two lakhs of rupees. Since the close of the year a suitable site has been selected for the new hospital.

North-Western Provinces and Oudh.

The statistics of the hospitals and dispensaries in the North-Western Provinces and Oudh for 1884 bear evidence of the fact that the year was an unhealthy one. During the year 236 institutions were at work, three of which were new ones. Of these, two were State supported, 202 were maintained by provincial and local funds, 21 were under private management, and 11 were chiefly supported by private individuals, but aided partly by State funds. Where possible arrangements were being made to have female patients and children prescribed for separately from the males. Complete statistics were received only from 214 institutions, against 212 in 1883, and at these the number of patients treated was 1,737,782 against 1,567,456 in the previous year, showing an increase in 1884 of 170,326. Of the total cases, 16·72 per cent. were under treatment for fever, 4·80 for dysentery and diarrhœa, 17·86 for skin diseases, 6·74 for respiratory diseases, and 5·50 for ophthalmia. The in-patients numbered 44,201, being more by 1,917 than in 1883, and among them there were 2,832 deaths, or 64 per 1,000 of the total number, against 2,549, or 60 per 1,000, in the previous year. Satisfactory progress continued to be made in the performance of surgical operations, which, it is reported, "has induced a widespread belief in the efficiency of modern surgery, and "has done much to attract patients to the hospitals." Minor operations rose from 78,403 in 1883 to 79,529, and major operations from 12,472 to 14,938, the latter number being nearly double that of 1881. The success of the operations was also very marked, for out of the total major operations, 11,143 were returned as cured, 1,973 as relieved, and 281 cases resulted in death against a corresponding mortality in 1883 of 296. Success is further indicated in the fact that of 6,366 patients operated on for cataract 4,592 gained good sight. It appears that the increased control which has been given to local boards over the medical institutions within their jurisdiction has not yet been productive of much practical change in any of the details of management; still in several districts some members were showing their interest in the dispensaries by giving them substantial aid and support.

Central Provinces.

There were 82 dispensaries at work in the Central Provinces during 1884, the same number as in the previous year. The management of those within municipal limits has recently been transferred to municipal committees, while all are practically maintained by local funds. The patients under treatment numbered 652,620 against 611,541 in 1883. This shows an increase in 1884 of 41,079 cases, which, however, was entirely among out-patients, for in-patients decreased from 7,545 in the preceding year to 6,961; and this decrease was "almost wholly due to a more careful observance "of the rules regulating admissions." Of the total cases, fevers, catarrhs, and rheumatic affections were more numerous than in 1883, which was attributed to the unusually heavy rainfall of the year; on the other hand, there was a decrease under bowel complaints. The number of deaths among the in-patients fell from 824, or 109·2 per 1,000, in 1883 to 624 or 89·6. The total number of operations performed in the course of the year was 18,341, of which 637 were of the major class as compared with 564 in 1883. There appears to be no doubt that the institutions are greatly appreciated by the people, though their popularity depends to a great extent on the hospital assistant in charge. "A popular hospital assistant means a crowded dispensary."

arar.

There were 42 medical institutions in operation in Berar during 1884, or one more than in the previous year. At these the total number of patients treated was 206,184, of whom 1,800 were in-patients, against 2,137 in 1883, and 204,384 were out-patients, against 193,227. The year being a healthy one accounted for the decrease in

attendance amongst in-patients. "But that there was no large decrease over the "figures of the previous year, which was pre-eminently an unhealthy one, may be "taken," Dr. Little, Inspector-General of Dispensaries, says, "as good evidence that "the people appreciate the dispensaries, and readily avail themselves of the means of "relief placed within their reach." Malarious fevers caused the largest number of admissions, being in the ratio of 20·4 per cent. of the total treated. Next in order of prevalence was ophthalmia (9·3 per cent.). "This affection," Dr. Little writes, "is most rife in the hot weather, due to irritation from the glare and to the impalpable "dust blown about at this season, which may contain, in a desiccated state, septic or "other irritant and putrid matter derived from a filthy village site." Next in order came skin diseases, with a ratio of 8·1 per cent. Most of the other diseases retained the same relative proportions as in previous years, excepting dysentery and diarrhœa, the cases of which were less, owing to the absence of cholera in an epidemic form in the province during the year. Of the in-patients, 1,567, or 87 per cent., were cured, 43, or 2·3 per cent., were relieved, and 66, or 3·6 per cent., died. The number of operations performed was 299 major and 7,328 minor, against 291 and 7,069 respectively in 1883. Of the major operations, which consisted chiefly in the setting of fractures, 267 ended in cure, 6 in relief, and 8 in death.

Assam.

Ten new dispensaries were opened in Assam during 1884, including one in the *kala azar* district of Goalpara, making a total of 39; and the number of patients was 107,136, or 29,576 more than in the previous year. This great increase was mainly due to the opening of the new institutions, but the attendance at the old ones increased by 11 per cent. As usual, more patients were treated for malarious fevers than for any other disease, namely, 16,935, or 3,711 more than in 1883; cholera cases rose from 599 to 1,614, owing to the increased intensity of the disease throughout the province; and small-pox cases numbered 121, against 68 in 1883. Skin diseases were very common, 14·9 per cent. of the total being treated under this head. In-door patients numbered 3,565, as compared with 3,294 in 1883, and among them there were 758 deaths, or 212·6 per 1,000, against 666, or 202·2, in the previous year. Both in major and minor operations there was an increase, the former amounting to 190, or 42 in excess of the number of 1883, and the latter 2,779 against 2,324. Of the major operations, 144 were cured, 13 partially relieved, and 16 died. "The disinclination of the Assamese to submit "to operations," it is stated, "owing to constitutional timidity, is a hindrance to "any rapid advance in this subject; but there is reason to believe that this aversion is "being gradually lessened, and that the prejudices and superstitions of the inhabitants "are being overcome by practical demonstrations of the utility of surgical measures." The Officiating Chief Commissioner states that much has been done of late years in administering dispensary relief and in improving generally the sanitary condition of the principal towns of the province, and he has no doubt that as the resources of the province and of the local boards increase improvement will continue.

British Burma.

In British Burma 31 dispensaries were in operation during 1884, three of which were new ones. The total number of patients treated was 169,741, or an increase of 18,668 over 1883. This increase, however, was almost entirely among out-patients, for in-patients, who numbered 13,574, were only 142 more than in the previous year. The most important causes of sickness were fevers, which were in the proportion of 16·57 per cent. of the total; skin diseases and injuries came next, with per-centages of 6·61 and 6·31, followed by respiratory diseases with 5·16. Deaths among the in-patients rose from 1,197, or nearly 90 per 1,000, in 1883 to 1,596, or over 117 per 1,000, in 1884. There was a marked rise in minor operations from 3,863 in 1883 to 4,201, but the number of major operations declined from 329 to 249; and of these latter, 202 ended in cure, 12 in relief, and 21 in death. It is stated that since these charities have come under the management of town committees, the people are not so ready to give pecuniary aid; but the institutions are on the whole popular, and receive constant supervision from the committees.

Lock Hospitals.

Bengal.

It was noticed in the report for 1883–84 that on the suspension of the Contagious Diseases Act in Calcutta the lock hospitals at Alipore and Sealdah were to be maintained as purely voluntary institutions. The returns of these hospitals for 1884 show a nominal decrease in cases of primary syphilis compared with the previous year, but the total was otherwise much greater than in any year since 1869. As

regards the effect which the withdrawal of the Act has had on the police force, the number of cases of venereal disease has increased from 1·46 per cent. of total strength in 1882 to 2·97 in 1884; and the men are reported to have suffered during the year from the most malignant types of the disease,—"a thing unknown in previous years." The effect on the garrison troops of Fort William was much more marked, the per-centage of venereal complaints on the mean daily strength having increased from 14·5 in 1882, and 28·0 in 1883, to 58·4; while the per-centage of cases of primary syphilis rose from 10·9 in 1883 to 30·24 in 1884, the highest ratio recorded in any year since 1870. Among the general population, venereal cases in the Calcutta hospitals and dispensaries were a trifle less than in 1883, namely, 10,020 against 10,147 in 1884; but still 1,246 in excess of the number of 1882.

Of the four cantonment lock hospitals in Bengal, the results obtained at Dinapore and Darjeeling show a considerable increase in cases compared with 1883, the admission-rates having risen from 145·16 and 27·14 respectively, in that year, to 265·21 and 170·12. On the other hand, there was a decrease in the admission-rates at Barrackpore from 268·2 in 1883 to 146·2, and at Dum Dum from 369·59 to 264·3. The cost of working the system in these four cantonments was, it is stated, considerably higher in 1884 than in the previous year, "and the fact remains that, notwithstanding "the powers which the police can exercise under the law, unlicensed prostitution "prevails almost as extensively as if there was no law or attempt at control."

Madras. The Contagious Diseases Act is reported to have worked smoothly during the year in Madras city. Out of 17,436 examinations 365 women, or a little over 2 per cent., were found diseased, "a result which shows that the class of registered prostitutes "was remarkably free from disease."

The average number of registered women at the seven military lock hospitals in the Madras Presidency during 1884 was 684, against 667 in 1883, and amongst them the number treated and the average daily sick was above the average, but the type of disease was much about the same. The number treated was 2,911 against 2,611 in the previous year, and the daily average sick rose from 159 to 171. The admissions for primary syphilis, the most serious of venereal diseases, were, however, considerably less than in the four preceding years. The rate of admissions from all forms of venereal disease amongst British troops was 272·12 per 1,000 of average strength against 274·24 in 1883. In five stations out of seven there was an increase, and in two a decrease in the admission-rates, the highest being 330·32 at Wellington. As in the case of the registered prostitutes there was a satisfactory decrease in admissions for primary syphilis amongst the troops. In his report for 1884 the Surgeon-General, of Her Majesty's forces gives a table showing the admissions for primary syphilis and gonorrhœa during the five years ending 1884 in the several stations where lock hospitals are established as contrasted with the admissions under the same headings where there are no lock hospitals. At the seven stations where lock hospitals exist the ratios of admissions per 1,000 of strength for the five years were, primary syphilis 112·70 and gonorrhœa 116·68; and at five stations where there are no lock hospitals the ratios were 50·19 and 76·80 respectively. "We are forced to admit by "a perusal of the figures," the Surgeon-General states, "that lock hospitals have "hitherto been kept up for the propagation of venereal amongst British soldiers, "though originally established with a very different intention. The greater prevalence "of venereal in stations where lock hospitals are established can be satisfactorily "accounted for. A registered woman rarely leaves the bazaar to ply her trade; in "many stations there is a place assigned to her in the bazaar and there she must "live. She is generally a prostitute from her earliest years; whereas the unregistered "woman is generally a villager, driven to prostitution for a livelihood, and she may "lie in wait for the soldier anywhere so long as she is not found out. She is invariably "diseased. In stations where there are lock hospitals she has no rival, as those "women, such as parcherry servants, grass-cutters, &c., who prostitute themselves "to supplement their wages are afraid to be seen out at night for fear of seizure and "compulsory registration. In the cantonments where there are no lock hospitals, "women can prostitute themselves when inclined without fear, and the health of the "soldier benefits by the rivalry which is so severely checked where lock hospitals are "established." This view, however, it must be observed, is by no means supported by the results in Bombay stations (see below).

Bombay. In Bombay City the Contagious Diseases Act is said to have worked satisfactorily during 1884. Disease was discovered in 3·8 per cent. of 12,361 examinations. As, however, 9·8 per cent. of the new registrations were found diseased, it is pretty clear

that among those who had been for any time under supervision its prevalence was but slight. "It is a noticeable fact," it is reported, "and one indicative of the value "of the Act that the 25,000 sailors who visit the port annually enjoy an almost entire "immunity from syphilis during their stay in Bombay. This circumstance is "doubtless due to the custom of this class of men to resort to licensed houses, whereas "the soldier, resident for some time in the place, has opportunities for forming "clandestine acquaintances, from which most of the contagion arises."

Lock hospitals were maintained at the same 12 stations in the Bombay Presidency as in previous years; but since the 1st of March 1885 those at Neemuch, Mhow, and Ahmedabad have been closed as an experiment. The average admission-rate for primary syphilis and gonorrhœa among the troops at stations with lock hospitals was 198 per 1,000, against 138 in 1883, and for stations with no lock hospitals, 377 per 1,000, against 278.

North-Western Provinces and Oudh.

As in the previous year 18 lock hospitals were in operation during 1884 in the North-Western Provinces and Oudh. The hospital at Moradabad, however, was open for only five months, and no detailed statistics of the working of the institution were received. Excluding this station the results compared favourably with previous years, the total admissions of soldiers to hospital from venereal diseases having fallen from 2,704, or 235 per 1,000 of strength in 1883, to 2,550, or 224 per 1,000, in 1884. The highest ratio was 327 per 1,000 at Meerut, and the lowest 122 at Chakrata. At Allahabad, Meerut, Roorkee, Naina Tal, and Jhansi, the protection afforded to the garrison against disease was more ineffectual than in previous years, but all other stations showed an improvement. The recorded statistics of the ten years in which the lock hospital system has been in force do not, it is stated, witness to any satisfactory results, for only in 5 out of 18 cantonments have the rules conduced to a substantial diminution in the ratio of venereal disease.

The daily average number of registered women declined from 979 in 1883 to 792, the decrease being attributable not altogether to the difficulty in obtaining women, but partly to the action of the Government in discountenancing expenditure on lock hospitals. With the decrease in the number of women there was a corresponding fall in the admissions to hospital, but the ratio of cases per woman rose from 2·35 to 2·57. This increase in the proportion of disease was confined, however, to disease of a minor description.

From the beginning of 1885 the lock hospitals at Allahabad, Meerut, Cawnpore, and Chakrata were by order of the Government of India closed.

Central Provinces.

The average number of women on the registers of the four lock hospitals in the Central Provinces during 1884 was 155, or two less than in the previous year, and the number of cases of admission into hospital among them from venereal disease was 319, or one more than in 1883. Among the troops the highest admission-rate was recorded at Jubbulpore, namely, 405 per 1,000 of average strength, against 261 in the previous year. This increase the medical officer attributed in a great measure "to the "number of women who practice prostitution in Jubbulpore; and although the city is "placed out of bounds for the troops, still they may gain access without attracting "notice, there being many inlets. For a short period during 1884 the restriction "against the troops visiting the city was withdrawn. The venereal diseases "increased, and the city was again placed out of bounds." The next highest ratio was 235 per 1,000 at Pachmarhi against 54 in 1883; but the comparatively small number of troops at this station (the average strength for the year being 123) makes the increase seem disproportionately large. At Kamptee there was an increase from 125 per 1,000 to 179, and at Saugor a decrease from 293 per 1,000 to 188. "The returns generally bear out the view so often expressed," the Chief Commissioner of the provinces states, "that the lock hospital system affords a limited protection, which "is beneficial so far as it goes. If the rules are at any time relaxed, the number "of patients in hospital is speedily increased, but even the best vigilance cannot "procure entire immunity."

British Burma.

Five lock hospitals were in operation in British Burma throughout 1884, three, viz., Rangoon, Thayetmyo, and Toungoo, being maintained and regulated by rules made under the Cantonment Act, 1880, for the protection of the troops; while at Akyab and Bassein hospitals were maintained by the desire and at the expense of the municipal committees of these towns chiefly for the benefit of the floating seafaring population. The lock hospital at Moulmein, which belonged to this class, was closed on the 1st June 1884.

As regards the protection afforded by the lock hospitals to European troops stationed in the province during 1884, it appears that although the average strength was reduced from 1,880 in 1883 to 1,628, the cases of venereal disease among the soldiers was 317, the same as in the previous year, the ratio per 1,000 of strength being 176·86, a higher ratio than in any of the preceding five years, and over 8 per 1,000 in excess of 1883. The increase was common to all three stations, but especially to Toungoo, where the ratio has been steadily increasing since 1880.

The average number of registered prostitutes at the six hospitals was 620, against 658 in 1883, and among them there were 956 cases of disease, or 272 less than in the previous year. In every hospital the per-centage of cases of disease to the average number of women on the register was less in 1884 than in 1883.

The admissions for venereal diseases in the dispensaries at the above six towns rose from 3,114 in 1883 to 3,380 in the year under review, and were one-third more than they were in 1879, a result "which would seem to imply," the Sanitary Commissioner observes, "that, like the military, the general population derive little or no "benefit from registered prostitution." The Chief Commissioner has directed that the authorities to whom is entrusted the working of the system should make more strenuous efforts to prevent the rules from becoming a dead letter.

Lunatic Asylums.

Bengal.

The number of persons treated for insanity in the five asylums in Bengal during 1884 was 1,139, exceeding that of the previous year by 58. Of these 208 were primary admissions and 24 were re-admissions, against 209 and 23 respectively in 1883. The cause of insanity was known only in 582 cases, 448 having been due to physical and 134 to moral causes. Recovery was effected in 90 cases, being at the rate of 9·77 per cent. on the mean daily population. This is a low rate of recoveries compared with 12·47, the average of the previous 10 years. Undoubtedly, the Inspector-General of Hospitals states, the longer chronic cases are kept in the asylums, the lower the per-centage of recoveries, while a certain number of criminal lunatics is a fixed quantity, and that these facts together tend to vitiate statistics. The health of the asylums was not so good as in 1883, the number of admissions to hospital having increased from 235 to 365, and the deaths from 52 to 87, the increase being principally occasioned by diarrhœa, dysentery, debility, and phthisis. "It is not a high mortality," the Inspector-General writes, "and could we but eliminate those deaths which right-"fully belong to 1883, the rate would be an average one. The healthy year 1883 "possibly prolonged the lives of the phthisical, the debilitated and senile lives, which "depend in a great degree, some altogether, upon meteorological conditions. Thus, "in 1883 2 deaths were placed to debility, 2 to old age, and 13 to phthisis; the "corresponding numbers for 1884 being 7, 4, and 26." Cholera was present only in the Dacca Asylum, where 3 cases were reported, 2 of which ended fatally.

Of criminal lunatics, 445 were under treatment against 423 in 1883; the fresh admissions numbered 86, or 19 less than in the previous year; the discharges rose from 50 to 61, and the deaths from 14 to 21, leaving 363 still in the asylums at the end of the year.

In the European Asylum at Bhowanipore 54 patients were under treatment, 25 of whom were admitted during the year, against 24 in 1883. In the course of the year 3 were discharged cured, 11 were sent to Europe under the Merchant Shipping Act, or otherwise, 4 were transferred to their friends, and 2 died, one being a case of decay in a hard drinker, and the other of acute mania in a woman.

Madras.

Each year witnesses to an increase in the number of lunatics to be accommodated in the three asylums of the Madras Presidency. The number treated in 1884–85 was 707, of which 214 were new admissions. Of these 91 were discharged cured, 33 were transferred to the care of friends, 8 were discharged otherwise, and 35 died, leaving 544 under treatment at the end of the year, or 51 more than the number remaining in the previous year. The death and sick rates continued to be satisfactory, though the former rose from 50·5 per 1,000 of average daily strength in 1883–84 to 67·1; but, taking into consideration the proportions of former years, the results of 1884–85 are looked upon as very satisfactory. Of criminal lunatics, there were 132 under treatment during the year, 30 of whom were fresh admissions. The working of the asylums continued satisfactory, and great improvements were made to the industries of the Madras and Calicut asylums by the addition in the former of printing, carpet making, carpentry, and blacksmiths' work, and in the latter of weaving, coir-rope making, fibre spinning, tailoring, &c.

As in previous years, there was a want of accommodation during 1884 in four out of the five lunatic asylums in the Bombay Presidency, the exception being Hyderabad, in Sind. The new asylum at Ratnagiri was still in course of construction, but it was expected to be ready for use in 1885. The total number of lunatics under treatment during the year was 920, as compared with 948 in 1883, of whom 315 were fresh admissions. The number discharged was 199, 61 as cured; and the deaths numbered 59, or 20 less than in the previous year. The general health of the patients was satisfactory, and there was no epidemic in any of the asylums. Ague, diarrhœa, dysentery, epilepsy, and debility were the diseases from which the patients chiefly suffered. Among the total 920 patients, the causes of insanity were known in 442 cases, being physical in 338, and moral in 104; excess in the use of intoxicating drugs was credited with 210 cases. Of criminal lunatics there were 116 confined against 107 in 1883; of these 16 were discharged before the close of the year, and 6 died. All the asylums, with the exception of that at Hyderabad, were inspected by the Surgeon-General with the Government of Bombay (Dr. Beatty), and he reported that they were conducted in an able and efficient manner. Bombay.

In the course of 1884, there were 497 lunatics under treatment in the two asylums (Delhi and Lahore) of the Punjab, 127 of whom were admitted during the year. Of these, 51 were cured, 19 were made over to their friends, and 41 died. The Superintendent of the Lahore Asylum reported that the year 1884 was as healthy as the preceding one, without epidemic disease, and that the number of deaths (23) was the same; but at the Delhi Asylum it was the most unhealthy year since 1878, and the deaths rose from 8 in 1883 to 18, the heaviest mortality being from pneumonia. The number of criminal lunatics treated in both asylums was 58. The Lahore Asylum being in need of an improved water-supply, arrangements have been made with the railway authorities for a supply of water brought by a pipe from their main to the asylum, and the work was being carried out. This asylum was also in much need of a ward for European lunatics, and it is satisfactory to learn that a new ward was completed during the year, and ready for occupation; six additional cells for violent lunatics were also completed. Punjab.

Since 1879, there has been a steady increase in the population of the four lunatic asylums of the North-Western Provinces and Oudh. In 1884 the total number under treatment was 1,279 against 1,205 in 1883, the fresh cases being 364. Before the close of the year 213 had been discharged or made over to their friends, 5 had escaped, and 85 had died, leaving 976 still in the asylums. The mortality was again highest at Lucknow, namely, 116·9 per 1,000 of average strength; Agra followed with a death-rate of 113·3, and Bareilly and Benares with 69·4 and 1·90 respectively. Of criminal lunatics, 261 were confined during the year, 61 being new admissions. The daily average strength of this class of lunatics rose from 196 in 1883 to 206, the increase being due to the extra caution that was exercised during the year in regard to their release when reported to have recovered. New wards at Agra for criminal lunatics were completed, and deficiency in accommodation was thereby remedied. North-Western Provinces and Oudh.

The total number of lunatics under treatment at the two asylums of Nagpur and Jubbulpore in the Central Provinces during 1884 was 321, of whom 71 were fresh cases, 30 being transfers from the Amraoti Asylum in Berar, which was closed by order of the Government of India. At Nagpur the lunatics numbered 174 against 129 in 1883, the increase being due chiefly to the transfer to this asylum of the 30 lunatics from Berar; and at Jubbulpore the number was 147, less than in the previous year by 21. At the close of the year there still remained 286 inmates in the asylums, 13 having passed out as cured, 3 being transferred to their friends, 9 otherwise discharged, and 10 having died, the same mortality as in the previous year. Of the deaths, Nagpur contributed 6 or 45·3 per 1,000 of daily average strength against 4 or 35·3 in 1883, and Jubbulpore 4 or 29·9 against 6 or 58·8. As in other asylums in India dysentery and diarrhœa were the chief causes of death. As regards the inmates of the Nagpur Asylum, the Superintendent states: "The general health, apart from mental disease, "has been good. This may fairly be due to the favourable conditions under which "they live, and under these come housing, clothing, feeding, conditions of labour, site "of asylum, and so forth. Every lunatic is weighed once a month in my presence, "and his or her then condition recorded; disease of an insidious nature must thus "come to light." The Jubbulpore asylum was also reported to have been very healthy during the year. No particular kind of sickness was prevalent. Central Provinces.

Assam. The Tezpur Lunatic Asylum in Assam had 67 patients under treatment on the 1st January 1884; and during the year 21 new cases were admitted, making a total of 88, or 5 less than in 1883. Of the 21 new admissions only 6 were natives of the province, the majority of the patients being natives of Bengal. In the course of the year 15 patients were discharged as cured, 7 were made over to friends, and 8 died. The medical history of the asylum, although not so favourable as formerly, showed an improvement on the results of 1883, the number of deaths having declined from 14 to 8. The asylum was visited in 1883 by a severe cholera epidemic, which resulted in 9 deaths; the disease reappeared on the 24th June 1884, and 5 cases occurred up to the 26th, when the attacks ceased. Of the 5 cases 1 terminated fatally. Besides cholera there were 7 deaths from general disease, viz., 3 from phthisis, and 4 from general debility and dysentery, which brings the total mortality to 135 per 1,000 of population, and to 380 per 1,000 of admissions into hospital. The Superintendent of the asylum attributed the great mortality to the impoverished condition of the inmates at the time of the admission. "These are grave records," the Sanitary Commissioner states. "Much is to be urged in respect of the bad "health in which so many inmates are received, and also that with so limited a popu- "lation fluctuation of rates will often be extreme; but the total of 66 deaths on 243 "admissions, since the asylum was opened eight years ago, gives the high figure of "271 per 1,000 . . . . The statistics of daily sickness in the asylum certainly "bear out the contentions that the extraordinary mortality is not caused by want "of proper care, food, clothing, &c. within the precincts. An admission rate of "1,486 per 1,000 and a daily average sick of 22 per 1,000 cannot be considered "excessive among a population who may be considered primarily diseased as a body; "and the type of ailment from which the lunatics suffer is only that of the ordinary "population."

British Burma. During 1884 there were 60 fresh admissions to the Rangoon Lunatic Asylum, British Burma, which, added to the 190 patients remaining at the close of 1883 gives a total of 250. In the course of the year 44 were discharged, 25 as cured, and 15 with improved mental health, and 23 died. Of the total treated 42·4 per cent. were suffering from acute mania, and 23·2 per cent. from melancholia. The daily average sick and mortality, namely, 10·66 and 23 respectively, were exceptionally high, the increase in the latter from 12 in the previous year being chiefly due to the hopeless condition in which several patients were admitted. The mortality as calculated on the daily average strength was 127 per 1,000 against 63·5 in 1883; but "the majority of those who died," the Superintendent reports, "had been for years in bad health, kept alive by "nourishing food and careful nursing, so that their deaths were expected; the greater "number of these having succumbed this year, we may look for less mortality in 1885." The employment of the patients was continued with success, and was more extended and varied in character than in the previous year.

Medical Schools.

Bengal. The total number of medical students reading in the medical schools of Bengal increased from 722 in 1883–84 to 804 in 1884–85, and the monthly roll number from 741 to 847. In the Calcutta Medical College, the session opened with 117 students; 14 students of previous years rejoined the classes and there were 86 new admissions, making a total of 217 students against 197 in the preceding year. At the close of the session 14 students passed their final L.M.S. and M.B. examinations, 29 hospital apprentices passed and left for regimental duties, while 2 senior and 4 junior scholars, 29 paying and 7 free students, ceased to attend. At the close of the session there were therefore 132 students on the rolls. For the first M.B. and L.M.S. examinations of the University of Calcutta, 16 candidates passed out of 36. For the second M.B. and L.M.S. examinations, 14 passed out of 25 candidates; two Native dhais and eight pupil nurses passed in midwifery. The results of the examinations at the four vernacular Medical Schools were also very favourable. At the Campbell Medical School, Sealdah, the number of students rose from 190 in 1883–84 to 207, of whom 87 were fresh admissions. All the third and fourth year students, numbering 56, passed the final license examination. At the Dacca Medical School 31 students passed the final examination and received their diplomas as civil hospital assistants. Sixteen students at the Temple Medical School, Bankipore, obtained their diplomas. And at the Cuttack Medical School 11 candidates went up for the final examination and all passed, obtaining licenses qualifying them for third class hospital assistants, or to become ordinary Native medical practitioners.

The Dacca Homœopathic School which was opened in 1882–83 had become very popular, so much so that a second institution was established in 1884–85, when the two schools had 168 pupils. After a three years' course the pupils are considered qualified to practice, and may expect to earn from Rs. 30 to Rs. 50 a month.

Madras.

With the close of the year 1884–85 the Madras Medical College completed the first half century of its existence. The strength of the institution at the beginning of the year was 215, including 12 female students, against 182, of whom 10 were females, in 1883–84. Of these, 120 males and 4 females were in the senior department, and 76 males and 7 females in the junior department, besides 7 casual students. It is worthy of note that one of the female students was in the Chemist and Druggist class. From the Senior department 59 candidates went up for the University examinations, when 15 failed. As a proof of the progress made by the college, it may be mentioned that about 96 students were to appear for these examinations in 1885. The fact also that three students succeeded in passing the M.A. examination, two in biology and one in physical science, is considered a further proof of the soundness of the instruction imparted in this college.

In the second department or Apothecary class, 36 students, including three females, appeared for the first or primary examination, and all passed except two apprentices and one female student. Three hospital apprentices and three female students appeared for their final examination, and all passed.

All the lady students are reported to have made creditable progress during the year.

Bombay.

In the Grant Medical College there were 370 students on the rolls during 1884–85, of whom 17 were females. The class for female students was only instituted in the previous year, and of the 12 who then formed the class, 10 continued their studies, and 7 others were admitted, one being an undergraduate. In the course of the year the curriculum was revised so as to allow of the students having two courses instead of one in all the more important junior subjects.

The number of male students rose from 238 in 1883–84 to 353; but the results of the examination were not so favourable as in the previous year. For the L.M.S. degree 38 students appeared, the same number as in 1883–84, and only 23 passed, 3 in the first and 20 in the second division, as against 5 and 23 respectively in the previous year. At the first examination there were 81 candidates, 20 only being successful, whereas in 1883–84 43 succeeded out of 93 candidates. Two candidates appeared for the M.D. degree, and one succeeded in obtaining the coveted distinction; 5 assistant surgeons were found qualified for promotion; and from the military pupils' class 8 fully instructed apprentices passed out as qualified for the grade of sub-assistant apothecary. In reviewing the events of the year, the Principal of the college draws particular attention to the large increase of numbers of matriculated students, who for the past five years had averaged 266, whilst in 1868 they numbered only 20. He also notices that the college is taxed almost beyond its strength to meet the demands on its teaching capacity, and he looks forward to the day when a college of experimental science, with laboratories fitted for scientific experiment and research, shall be found in Bombay.

The medical schools at Poona, Ahmedabad, and Hyderabad continued to progress. The attendance at Poona was slightly less than in the previous year, but at the other two it was greater. The results of the examinations were also satisfactory. Twenty-two students from Poona, and 13 from Ahmedabad passed their final examination, against 16 and 15 respectively in 1883–84; and for the first time the Hyderabad Medical School submitted its pupils to the test of the final examination. The pupils of this school consist of native medical pupils and High School pupils, and the object in view is to provide the province of Sind with qualified practitioners, as well as to recruit the local subordinate medical service with suitable candidates. Eight of each class of pupils passed the final examination.

North-Western Provinces and Oudh.

The Agra Medical School during 1884–5 was attended by 111 students, whose progress on the whole appears to have been satisfactory. In the senior class all but five of the 28 pupils passed their final examination. In the second class, composed of 34 pupils, three of whom were females, there was an improvement in the number of students who passed at this stage, the first of the final examinations. The female students of this class, who were all Native Christians, did not turn out so well as was hoped, but they were encouraged to persevere and complete the school course. In

both these classes the military sections were reported to be inferior to the civil. The third class consisted of 21 civil and private pupils, who during the previous year had been attached for practical instruction to a dispensary. The fourth or junior class contained 31 pupils, 8 of whom were females. There were only 15 civil pupils in this class, and, as a body, they were reported to be inferior to those admitted in the two preceding years. The prevalence of cholera at the time of the entrance examination is reported to be the cause for the deficiency in numbers and the inferiority in general attainments of the candidates selected from a smaller field. The most notable feature of the administration of this school during the last few years has been the formation in 1882–83 of a class for female students. At first only Native Christians joined, but the fact that candidates in fair numbers, amongst whom were Hindus and Muhammadans, were coming forward, bids fair to the ultimate success of the scheme.

VII.—SANITATION.

Civil.

During 1884 much attention was paid by the Government of Bengal to the sanitary condition of Calcutta and its suburbs, and steps were taken with the view of remedying existing evils. As noticed in the Report for last year (1883–84) a Commission was appointed by the Lieutenant-Governor to enquire into and report on the adequacy or otherwise of the provisions made by the Municipal Commissioners for the cleansing and conservancy of the town. An exhaustive inquiry was made, and the Commission submitted a valuable report, with their recommendations for various improvements. Bengal.

The supply of filtered water to Calcutta was considerably increased during 1884–85, the average daily supply being 8,207,330 against 7,975,960 gallons in the previous year; there was also an increase in the house connections from 15,187 to 15,830. Since 1879 the supply has increased about 11 per cent., while the house connections have increased upwards of 31 per cent. The sewerage of the town was almost completed, and considerable progress was made in the structural improvement and subsoil drainage of bustees. With reference to the improvement effected in the drainage of bustee lands, the Health Officer states: "One steady object has been held in view "throughout the year, viz., to confine sewage in surface drains of masonry falling "into the sewers, and to prevent as far as possible its escape over the surface." Good progress was made in improving privies and latrines. The work of tank and well filling and the substitution of bathing platforms was pushed on with energy, as was also the surface conservancy of bustees. Much attention was paid to the improvement of cowsheds and cattlesheds, and good work was done in structural improvements of streets.

The income of the Municipalities of Bengal, excluding Calcutta, for the year 1884 amounted to about 320,000*l.* against 336,000*l.* in the previous year. Notwithstanding this diminution the apportionment for sanitary works was raised from 34 per cent. in 1883 to 38 per cent., the increase being spread over all heads except conservancy establishment and water-supply. The most important work of the year under water-supply was the completion of the Burdwan works, a measure which is reported "to be of "great benefit to the inhabitants of the northern part of the town, in which pipes "have been laid and hydrants set up." At first many of the inhabitants were unwilling to use the filtered supply, but opposition soon died away, and 99 per cent. of them were using it. In Dacca further improvements were made in the filter beds, and the munificent Nawab Assanoollah had, in commemoration of the visit to India of their Royal Highnesses the Duke and Duchess of Connaught, extended the waterworks northward. This has proved a great boon to a crowded locality. With reference to this work the Army Sanitary Commission remark: "India at present affords abundance "of opportunities for men of wealth and influence to bestow similar benefits on their "poorer fellow subjects. The example is one which should be commended and "followed." The works in connection with the water-supply of Bhagulpore town were being carried on, and Government has lent the services of the Superintending Engineer and his subordinates for the undertaking free of cost. Arrangements were made for the preparation of plans and estimates of an approved scheme of water-supply for Howrah, in which other river-side towns were to join. In Nuddea district improvement of the water-supply was under inquiry with the object of ascertaining, if possible, to what extent the prevalence of malarial fever and other zymotic diseases there was due to bad water.

During the year many drainage schemes were prepared, and some, where funds would admit, were sanctioned. Further improvements to the drainage of the fever-stricken district of Nuddea were effected. The drainage works of Moorshedabad city which were commenced in 1883 were completed, and further improvements were under consideration. Steps were being taken to improve the drainage of Raniganj town in Burdwan. The question of radically improving the drainage of Patna municipality was under consideration, and in defect of means for a general drainage scheme provision has been made for keeping the rainfall from stagnating by a system of surface pucca drains; these works are reported to have proved of the greatest service.

Little appears to have been done to improve the sanitation of villages. A suggestion was made by the magistrate of Shahabad to the effect that Government

might take special sanitary action in its villages; this suggestion the Government of India considered worthy of consideration, and the Army Sanitary Commission stated that if the course were followed, "health and life would be saved, and an example set "forth that the Government meant what it advocated to be carried into action." Amongst the miscellaneous sanitary operations of the year, the chief event was the passing of the new Bengal Municipal Act III. of 1884, which contains excellent sanitary regulations relating to sewage and other matters. Another important Act calculated to benefit sanitation, the Bengal Local Self-Government Act, was passed in April 1884, and has since received the sanction of the Supreme Government.

Madras.

The water-supply of the town of Madras was seriously affected in November 1884 by a cyclone which completely breached the Red Hills Reservoir, causing the loss of the whole store of water. A supply was, however, obtained from another source, the Koratur tank, till February 1885, when a temporary bund at Red Hills was erected, and the water was raised above the level of the off-take pipes, and the town was again supplied. Advantage was taken of the low level of the water in the lake to commence the off-take tower, which is a part of the new water-supply scheme, in the deepest part of the tank, and the work was vigorously pushed on. Extensions of the existing water-supply were carried out in other parts of the town. The Black Town drainage scheme was making progress, and the pumping station at Royapuram was formally opened on 30th June 1884. The surface drainage of the eastern portion of Black Town between Popham's Broadway and the sea was almost completed, more than 70,000 feet of surface drain having been laid down in the 15 months ending March 1885. In the diversion of drains from the Coum Canal, a plot of land in Poodoopett, over 22 acres in extent, was purchased, and, a parcherry being removed from it, was levelled to serve as a sewage farm for the disposal of the contents of a large drain which flows into the Coum.

In other parts of the Madras Presidency the sanitary work of the year 1884 consisted chiefly in the repairing and cleansing of tanks and wells, in the repair and construction of latrines, drains, roads, &c., and in improving village sites. In the municipalities, excluding Madras town, the sanitary allotment was about 65,000*l.*, or 33·9 per cent. of their estimated income, against 57,000*l.*, or 33·2 per cent. in 1883–84; but of this allotment only about 38,000*l.* were utilized at the end of the year. A similar state of things occurred in the local fund circles, where out of the sanitary grant of about 37,000*l.*, equal to 26·5 per cent. of their aggregate available income (one-third land cess), only 19,000*l.* were expended up to the end of December 1884. Steps, however, have been taken by the Government to impress upon the various authorities the necessity of utilising the whole of the sanitary allotments during the year for which they are sanctioned, and better results are expected in the future. An Act was passed during the year (the Madras Local Boards Act, 1884) which "provides "for the prohibition and removal of obstructions, and the cleansing of tanks, streams, "wells, and unwholesome buildings and lands in all rural areas," and under its powers the Sanitary Commissioner expects that greater attention will be paid to town and village sanitation. "But the great want in all villages," the Army Sanitary Commission point out, "is cleansing and keeping clean, provision of suitable accom- "modation for cattle to enable them to be removed from compounds and houses, and "providing village water supplies;" and these important points they hope will not be overlooked.

Bombay.

Various sanitary improvements were completed during the year in Bombay Municipality. The construction of the catchment channels on the slopes above the Vehar and Tulsi lakes, and the raising of the Tulsi dams were brought to a close; the Bhandarwada Reservoir and the filter beds at the Malabar Hill Reservoir were completed, and the latter were in use nearly the whole year. The roofing of the latter reservoir, and the laying of a new main, from Behar to the outlying portions of the island, were also in progress, and the Municipal Commissioner believes that when these works are completed the quantity and quality of the water distributed over the city will be as ample and as perfect as it is possible to make them with the present sources of supply. Since the close of the year the Corporation have sanctioned the construction of an additional artificial lake at Tansa, and, when the project is carried out, "the difficult "question of water-supply to the present city of Bombay and to any possible future

"Bombay will be set at rest finally and for ever." A number of waste water meters were fixed during the year, and much waste was thereby prevented.

In the drainage of the city considerable progress was made during the year under review in the construction of main sewers. The laying of the pipe sewers in the first section of the drainage scheme was completed, but owing to the want of house connexions these sewers were practically useless. The surface drainage to carry off the storm waters, which often flood the low-lying parts of the town, was nearly completed, but during the rains the sewage of the city is still carried in these drains, the result being a serious nuisance on part of the flats. His Excellency the Governor in Council therefore trusted that the connexion of the sources of sewage with the new main drains, which is necessary for the abatement of this nuisance, would be completed without avoidable delay. He further hoped that the inhabitants of Bombay would realise the soundness of the opinion that the value of a thorough system of drainage is second only to that of a copious and pure supply of water.

No sanitary work of any magnitude was undertaken in any other part of the Bombay Presidency during 1884, but a good deal was done in improving the general sanitary condition of localities. Out of an income of 298,667*l.* the municipalities, excluding the city of Bombay, expended 66,081*l.* on conservancy.

In the local fund circles sanitary work consisted chiefly in providing and repairing of wells, on which about 13,000*l.* was spent. At the suggestion of the Sanitary Commissioner, a Consulting Sanitary Engineer (Colonel Ducat, R.E.) for the Presidency, was appointed during the year, and municipalities were informed that his services would be placed at the disposal of such as might desire them for the preparation and execution of designs for sanitary works on their undertaking to pay his salary and allowances during the period he might be so employed. The municipalities of Ahmedabad and Hyderabad in Sind have already applied to Government for his services, the former in connexion with water-supply and sewerage, and the latter city, which has a good water-supply, for a sewerage scheme. The Army Sanitary Commission have no doubt that, if the services of this officer are made use of by municipalities, much public good will follow.

The Sanitary Commissioner, Deputy Surgeon-General Hewlett, testifies to the satisfactory work of the civil surgeons, who during the year visited 102 towns and 4 villages, and made many valuable suggestions which he hoped would lead to the improvement of sanitation of towns and villages in the vicinity of the large towns and cantonments.

An important memorandum has since been drawn up by the Sanitary Commissioner for the information and guidance of village patels throughout the Presidency for the purpose of showing them what the several insanitary conditions which obtain in villages are, and how they should be remedied; and also to instruct them in what cases they can, when authorised, put in force the powers conferred on them by existing law. The Governor of Bombay trusts that the circulation of this "highly "valuable memorandum, and the explanation of its provisions at high schools and "colleges, will contribute to enlighten the public on subjects of vital importance, and "stimulate co-operative and private initiative. Insanitary conditions of houses are a "serious evil, but it would be impossible to enforce legislation throwing expenditure "on individuals who could not afford it. Education and the influence of good "example will bring about the desired results in accordance with the necessarily slow "process of assimilation of scientific requirements."

Punjab.

Amongst the more important sanitary works executed or undertaken during the year in the Punjab, may be mentioned the Sanjauli Reservoir at Simla, calculated to hold 2,000,000 gallons, which was so far advanced at the end of the year that water could be stored in it. There is another reservoir capable of storing 1,180,000 gallons; together these two will give an aggregate supply of 4½ gallons a head to 16,000 people. A portion of the drainage of this hill sanitarium was also commenced, at an estimated cost of 11,000*l.* At Amritsar the drainage works for the removal of storm water from the city and suburbs, and for the drainage of certain jhils near the civil lines, were drawing to completion. At Delhi schemes for water-supply and drainage were prepared and submitted to Government; the former was approved at an estimated cost of about 100,000*l.*, but the drainage project, amounting to 40,000*l.*, was still under consideration. In the suburbs of Delhi drainage works were restored at a cost of 1,500*l.* At Peshawar the Bárá river, which runs through the city, was cleansed and converted from a filthy channel into a comparatively clear stream, fit for watering streets, &c.; a scheme for supplying the city with pure water was also under considera-

tion. Plans and estimates for the drainage of Hoshiarpur were waiting the sanction of Government, and the project for a circular drain for the city of Sialkot was sanctioned. Besides the above, a great number of minor improvements in connexion with conservancy, water-supply, drainage, &c., were carried out in the municipalities at an expenditure of 92,000*l.*, equal to about 32 per cent. of their income. In the course of the year the Sanitary Commissioner did a large amount of useful inspection work, when he advised the members of the newly-elected boards under the Local Self Government Act on the sanitary improvements needed, on the utility of the practice of vaccination, and on matters of domestic and personal hygiene.

North-Western Provinces and Oudh.

"With few exceptions no sanitary work of any magnitude was executed during the year in the North-Western Provinces and Oudh, the funds at the disposal of municipalities being, as a rule, it is stated, barely sufficient to meet absolutely necessary expenditure for the repairs of roads and drains, and other minor work; but almost all the municipalities appear to have devoted a portion of their income to sanitation. At Bareilly 2,600*l.* was expended on works, chiefly in connexion with the drainage of the city. At Saharanpur a loan of 5,000*l.* was applied for to carry out a complete drainage scheme for the city. In Azamgarh and Gorakhpur also important drainage operations were being carried on. At Lucknow the water-supply scheme, prepared in 1883, was completed, and the question of experimental artesian borings was under the consideration of the Government. Good inspection work was done during the year by the Sanitary Commissioner, who found that "works of sanitary improvement continued "to be effected in almost every centre of population; and I have reason to think the "increasing powers and the authority of the municipal and local authorities, is "resulting in increased attention to and more effectual performance of those works, "so important to the welfare of the people." The Government of India in their orders on the Sanitary Commissioner's report state that "no important steps appear to "have been taken to improve the sanitary condition of villages in any district." The subject has since been brought to the notice of district officers and they have been requested to endeavour to induce villagers to adopt some simple rules of sanitation.

Central Provinces.

There is little to record under the head of sanitary improvements in the Central Provinces. The work of the year was of minor importance, consisting chiefly in cleaning tanks, wells, and drains, repairing and constructing latrines, &c. During the year the Sanitary Commissioner inspected several towns and a considerable number of villages with reference to the village conservancy rules recently passed by the Chief Commissioner; and he found that in some sanitary measures were already being attended to. The Army Sanitary Commission testify to the importance of these rules, which, "if obeyed continuously," they say, "will remove many disease causes;" and they express concurrence in the summing up of this matter by the Chief Commissioner of the Province, who is quite aware that much has to be done in improving the sanitation of towns and villages. He has insisted, when necessary, on municipal committees doing their duty in this matter, and he will not permit this duty to be neglected. But he also realises that much good work has been done, and he is convinced that to have such work carefully ascertained and acknowledged does much to encourage those who are engaged in it. "In regard to village sanitation, energy must "be accompanied with patience, but greater progress may, no doubt, be looked for "now that we have responsible mukaddams in every village, and that the agency of "local boards can be made use of."

Berar.

The expenditure incurred on sanitary improvements in the municipalities of Berar during 1884 amounted to 15,700*l.*, the principal items being conservancy, drainage, and water-supply. Besides this outlay, several important permanent sanitary works were being carried out. The two large schemes for providing the towns of Amraoti and Khamgaon with a good supply of water were approaching completion. The Kalapani tank, to supply the town of Amraoti with water by means of pipes, at an estimated cost of 30,000*l.*, has been completed, and arrangements were being made for taking the water into private houses. The municipalities of other towns were seriously considering the question of their water-supply, and it was hoped that in the case of Akola and Ellichpur, where schemes for considerable extension and improvement of their present supply are feasible, it would be found possible shortly to undertake them. With regard to village sanitation, the Sanitary Commissioner states

that since the introduction of the rules promulgated by the Resident in 1880 "con-
" siderable improvement has undoubtedly been effected, and where these rules are
" observed the village site is clean and the surroundings undefiled . . . . The minds
" of the people are gradually becoming familiarised with the fact that what is required
" under these rules is for their own benefit, and no opportunity is lost of impressing
" this upon them, and that it is not merely for a whim of their rulers that these simple
" sanitary precautions are enforced." Steps were being taken for the supply of Dr. Cuningham's Sanitary Primer, as a class book, to all schools.

Assam.

Little appears to have been done in the way of sanitary improvement in the province of Assam during 1884. For all purposes the expenditure was 6,900*l.*, of which amount only a sixth part was devoted to drainage and water-supply. The only works calling for notice are the Gauhati water works, which were still in progress, and the Goalpara drainage scheme, the main channels of which have been already completed and at work for two years. The latter undertaking has been placed in the hands of the local board with a view to its more speedy completion. Although the record of sanitary improvements is small, there appears to be every desire to forward improvements if means were available. The Army Sanitary Commission, however, think "that more activity in the localities themselves in forwarding the work, even
" with the means at disposal, might very well be shown. The people should learn
" that in small places whatever is required for protecting health ought to be done
" by the people themselves, and that, if they do not choose this course of action, they
" must pay somebody else to do the work. This ought to be the duty of every
" municipal government."

British Burma.

No sanitary works of any magnitude were undertaken in British Burma in 1884; but some important projects were under consideration. At Rangoon an elaborate scheme for the drainage of the town at an estimated cost of 170,346*l.*, or with a supplementary high pressure water-supply at 180,035*l.*, was under consideration. At Prome a sum of 12,428*l.* was spent in the course of the year on the new water-supply works which were practically complete. At Pegu a general scheme of surface drainage was commenced at an estimated cost of 2,500*l.* In most of the other municipalities works of minor importance were carried out, and town committees generally were evincing much interest in the sanitation of their towns. Nothing, however, appears to have been done to improve the sanitary condition of the villages in the province, but the Chief Commissioner's attention has been directed to the matter by the Government of India. The total amount expended by the municipalities during the year on sanitary work was 15,149*l.*, but of this sum 8,454*l.* were allotted to markets and burial grounds, leaving less than 7,000*l.* for sanitary work properly so-called.

Military.

Bengal.

The total expenditure on military works in the Bengal Command during 1884–85 was 575,003*l.*, against 673,532*l.* in the previous year. This is the only information given by the Sanitary Commissioner with the Government of India, owing to the details of works executed or in hand not being available at the time of the publication of his report.

Madras.

The Surgeon General of Her Majesty's forces in Madras, in his report for 1884, gives an account of the sanitary condition of the stations. The account, the Army Sanitary Commission state, "does not call for remark, as there seems every disposition
" to render the barracks and stations healthy, and indeed the low death and inefficiency
" rates of 1884 show how much good work has been done." Nevertheless, as they point out, there are some few cases in which improvement is much needed; but these, it is satisfactory to learn, were under the consideration of the authorities.

Bombay.

The expenditure incurred on military sanitary works in the Bombay Presidency during 1884 amounted to 9,888*l.*, against 17,473*l.* in 1883. Large sums were expended on improvements in the cantonments at Ahmedabad, Nasirabad, and Aden, while in several other cantonments minor works were carried out. In discussing the sanitary condition of the cantonments, as described in the report of the Surgeon General of the Bombay troops, the Army Sanitary Commission remark that there is evidence in the report "that the chief elements in the sanitary state of the stations are becoming
" better understood, and their importance to the health of the troops duly appreciated.

"Much good work has been done, with a corresponding saving of life and efficiency, "which is not shown in the statistics, because data are included which belong to the "Command as a whole, and the data regarding Quetta and the troops on march in "Southern Afghanistan have to be discussed for practical purposes as a separate "problem." The excessive sickness and mortality among the troops stationed at Quetta during 1884 have already been noticed. In consequence of the unhealthiness of this station the Sanitary Commissioner of Bombay, Deputy Surgeon Hewlett, paid a visit to the district in February 1885, with the view of reporting on the sanitary condition of the cantonment. He submitted a report containing several important recommendations, which are now under the consideration of the Government of India.

October 1886.

ABSTRACT

OF

SANITARY AND OTHER REPORTS

FOR

1884.

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1884.

(DR. B. SIMPSON.)

European Troops.

The health of the European troops during the year 1884 was not so favourable as it had been during the previous year, but the health statistics for 1883 were unusually favourable. Sickness and mortality in 1884.

Abstract of Statistics of European Troops in India for the last seven years 1878 to 1884, and for the ten-year period 1870–79.

Year.	Strength.	Ratio per 1,000 of Strength.				
		Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
1870–79	577,416	1,475	60	19·34	43	62
1878	56,475	1,651	68	21·46	45	66
1879*	49,582	1,977	78	24·28	49†	73†
1880*	51,796	1,789	74	24·85	26†	51†
1881‡	58,728	1,605	70	16·86	38	55
1882	57,269	1,446	65	12·67	33‡	45
1883	55,525	1,336	63	10·88	33	44
1884	54,996	1,513	67	12·56	32	44

* Excluding troops serving in Afghanistan. † Including troops in Afghanistan.
‡ Calculated on the strength obtained from Annual Returns.

The admission-rate for the year under review, 1,513 per 1,000, was above the average of 1870–79, a period for the most part undisturbed by military operations on a large scale. The daily average sick ratio, 67 per 1,000, was correspondingly increased. Notwithstanding this increased incidence of sickness, it is satisfactory to find the total death-rate, 12·56 per 1,000, considerably below the average of the last ten-year period. The mortality was 1·68 per 1,000 greater than that of 1883, which is the lowest on record. The loss to the army by invaliding was nearly 1 per 1,000 less than it was during 1883, the total loss to the army from death and invaliding being 44 per 1,000, the same as it was during 1883, or 18 per 1,000 less than the average loss during 1870–79.

The same may be said generally of the health of the British troops of the Bengal Presidency. Sickness was more prevalent than it was during 1883, as is evidenced by the increased admission and daily sick ratios. The admission-ratio, 1,662 per 1,000 of an average strength of 33,486, is greater than the average ratio during 1870–79, but is less than the average of the preceding 10 years (1860–69), which was 1,755 per 1,000. The daily sick ratio, 70, exceeds the averages of both decennial periods. The mortality from all causes equalled 11·68 per 1,000, a ratio almost identical with the very favourable result of the preceding year, which was the lowest on record. Loss by invaliding, 32 per 1,000, was somewhat greater than it had been during the preceding year, but less than the average loss from this cause in 1870–79 by 9 per 1,000. The total loss to the army from death and invaliding was 44, or 18 per 1,000 less than the average of the ten-year period.

The health of the British troops of the Madras Presidency was more favourable than in either of the other two Presidencies. The admission-rate, 1,109 per 1,000 of an average strength of 10,785, was greater than the ratio of the previous year, but below the ten-year average of 1870–79. The daily sick ratio, 57, was less than usual. The total mortality was remarkably low, viz., 8·53: this ratio is the lowest on record for the Madras Army. Cholera was but little prevalent, and occasioned a mortality of 0·93 only. The loss by invaliding (32 per 1,000) was 17 per 1,000 less than the average of 1870–79, and the total loss by death and invaliding, namely, 40 per 1,000, was 27 per 1,000 below the decennial average.

In point of sickness the Bombay troops stand between the Bengal and Madras armies, but in point of total mortality they showed the worst results. The admission-rate, 1,455 per 1,000 of an average strength of 10,725, though less favourable than that of the preceding year, compares favourably on the whole with recent ratios. The daily sick ratio, 65 per 1,000, was, however, considerably above the average of 1870–79. The total mortality, 19·30, was considerably higher than usual, but this was due in a large measure to the high death-rate from cholera, 4·85, a ratio higher than that of any of the previous years, and more than three times greater than the averages of the ten years, 1870–79, viz., 1·53 per 1,000. In addition, however, to cholera, enteric fever and remittent and continued fevers contributed considerably higher death-rates than those of the preceding year. Loss by invaliding, namely 31 per 1,000, was less than usual, and hence the total loss, which would otherwise have been heavy, was 51, or only 3 per 1,000 greater than the low ratio of the preceding year and 7 per 1,000 less than the average total loss during 1870–79.

The troops stationed in Southern Afghanistan belonged mainly to the Bombay Army, and the statistics relating to them are included in those given in the preceding paragraph. As the conditions and climate under which this section of the Bombay Army serves are peculiar, it is interesting to compare the health of the soldiers serving there with those serving elsewhere in the Bombay Command. The admission-rate in this section of the Bombay Army with an average strength of 1,441 men was 2,056, the daily sick ratio 83, and the total mortality 68·70. It is thus seen that the health of these soldiers was considerably worse than that of the Bombay Army as a whole, and all these ratios are higher than the corresponding ratios for the British Army of India as a whole. Malarial fevers were the chief causes of admission: these accounted for 865 per 1,000 of the total admission-rate. The chief cause of mortality was cholera, the deaths from which were 27 per 1,000. The incidence of this disease in these parts is characterised by remarkable intermittence and virulence. In 1879 the disease attacked the troops quartered there, causing a mortality of 32·69 per 1,000, but between that time and 1884 it remained in complete abeyance. But even excluding cholera, the mortality from all other causes was high, viz., 41·63 against 15·47 in 1883. Enteric fever, malarial fevers, apoplexy, sunstroke, dysentery and respiratory diseases, all contributed much higher death-rates than in the preceding year.

The chief causes of admission into hospital in the three Presidencies are shown in the following table:—

Bengal.		Madras.		Bombay.	
1. Malarial fevers	683	1. Venereal diseases	307	1. Malarial fevers	504
2. Venereal diseases	291	2. Malarial fevers	166	2. Venereal diseases	292
3. Wounds and accidents	124	3. Wounds and accidents	114	3. Wounds and accidents	115
4. Abscess and ulcer	91	4. Abscess and ulcer	87	4. Respiratory diseases	82
5. Respiratory diseases	79	5. Dysentery	56	5. Abscess and ulcer	76
6. Diarrhœa	51	6. Respiratory diseases	46	6. Diarrhœa	53
7. Rheumatism and rheumatic affections.	51	7. Rheumatism and rheumatic affections.	46	7. Rheumatism and rheumatic affections.	41
8. Hepatitis	26	8. Diarrhœa	42	8. Dysentery	26
9. Dysentery	22	9. Hepatitis	36	9. Hepatitis	18
TOTAL OF THE NINE	1,418		900		1,207
TOTAL FROM ALL CAUSES	1,662		1,109		1,455

Malarial fevers in all three Presidencies gave rise to a large proportion of admission, and in all three the ratios for the year under review were greater than those of the preceding year, though the excess was greatest in Bengal. In the foregoing table it

will be seen that the admission-rate for malarial fevers in the Bengal Presidency was 633 per 1,000, an unusually high ratio, exceeding the decennial averages of 1860–69 and 1870–79, which are 633 and 607 respectively. In the Madras Presidency these fevers gave rise to an admission-ratio of 166 per 1,000, which is below the average of 1870–79, viz. 266. Similarly the Bombay ratio, 504, is below the decennial average, viz., 660. Venereal diseases are also a prolific cause of admission, especially in the Madras Presidency, where they indeed head the list of the chief diseases giving rise to admissions. The decennial average admission-rates for these diseases in the three Presidencies are—Bengal 209, Madras 198, and Bombay 191, and the ratios of 1884 exceed these averages in all Presidencies—in Bengal by 82, in Madras by 109, and in Bombay by 101 per 1,000. Wounds and accidents come next, giving the highest ratio in Bengal (124), whilst in Madras and Bombay the ratios are practically the same (114 and 115). These ratios exceed those of the preceding year to a small extent. Respiratory diseases were most prevalent in the Bombay Army. Compared with the preceding year the admission-rates for these diseases were higher in the Madras and Bombay Presidencies, and lower in Bengal. This result is unusual, for the decennial averages are—Bengal 84, Madras 57, and Bombay 64. It is thus seen that in the Bombay Army alone the average was exceeded. Dysentery and hepatitis were more prevalent in Madras than in Bengal and Bombay.

The chief causes of mortality in the British Army of the three Presidencies are stated and contrasted in the following table:—

Deaths from	Bengal.						Madras.						Bombay.					
	1884.	1883.	1882.	1881.*	1880.*	1870-79.	1884.	1883.	1882.	1881.	1880.	1870-79.	1884.	1883.	1882.	1881.*	1880.	1870-79.

* Excluding troops in Afghanistan and on the march. † Including deaths from intermittent fever.

Enteric fever heads the list of diseases, giving rise to the largest proportion of deaths in the Bengal Army alone. During the preceding year this disease stood first in all three Presidencies. The proportion of mortality due to enteric fever in the Bengal Army was 3·31 per 1,000, a larger ratio than in any of the preceding four years and considerably above the average mortality during 1870–79. The next highest ratio, 2·05, is recorded in the Bombay Army. This ratio is higher than that of the two preceding years and also exceeds the decennial average. The ratio of the Madras Army, 1·67, exceeds the decennial average slightly. Compared with decennial averages, cholera was less prevalent than usual in the Bengal and Madras armies, but was more than usually prevalent in the Bombay Army. The unusually high mortality from cholera in the last-mentioned Army has already been alluded to, and will be referred to again in a succeeding paragraph. Hepatitis was as usual most fatal in the Madras Army, where the mortality from it amounted to 2·04, the largest mortality ratio from any one cause. This ratio is still, however, below the decennial average (3·16). In the Bengal Army deaths from this cause amounted to only 0·84 per 1,000 against a decennial average of 2·04. The Bombay Army recorded an intermediate ratio of 1·03 against a ten-year average of 1·71. Of the diseases enumerated in the above table as being the chief causes of mortality enteric fever alone gave rise to higher death-rates than the decennial averages in all three Presidencies. The total absence of mortality from malarial fevers in the Madras Army is noteworthy. In the Bombay Army no less than four of the six diseases enumerated in the table showed higher death-rates than the decennial averages, viz., cholera, malarial fevers, enteric fever, and dysentery in the order of excess.

The geographical groups into which the Bengal Army has been divided (excluding convalescent depôts in which small bodies of troops are located for a few months of

the year only) are enumerated in the following table, together with their admission and death-rates for a series of years:—

Period.	Ratio per 1,000 of strength.													
	Bengal Proper.		Gangetic Provinces and Oudh.		Meerut and Rohilkund.		Agra and Central India.		Punjab.		Hill Stations.		Bengal Presidency.	
	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.
1860–79	1,321	29·57	1,615	28·59	1,576	26·61	2,169	38·48	1,741	25·24	1,069	14·78	1,755	29·98
1870–79*	1,311	14·43	1,410	20·06	1,461	18·31	1,530	18·41	1,847	20·71	1,044	12·23	1,522†	21·00†
1880*	1,469	16·03	1,494	29·32	2,011	22·98	1,935	15·07	2,126	36·41	1,258	20·75	1,818	27·73

* Excluding troops in Afghanistan and on the march. † Including troops in Afghanistan and on the march.

Of these groups sickness as compared with the approximate averages of the 20 years, 1860–79, was more than usually prevalent in the Meerut and Rohilkund, Punjab, Hill Stations, and Agra and Central India groups in the order of excess of admission-rates over approximate averages. Malarial fevers and venereal diseases in all groups contributed most largely to the total admission-rates. Malarial fevers, on the whole, gave rise to from three to four times as many admissions in the Meerut—Rohilkhund, Agra with Central India and Punjab groups, as in the Bengal, Gangetic Provinces, and Hill Stations groups. Venereal diseases gave rise to the largest proportion of admissions in the first three groups. Respiratory diseases were most prevalent in the Punjab, Hill Stations, and Meerut and Rohilkund groups in the above order.

Compared with the ratios of the preceding year, the death-rates in the Bengal, Meerut, Agra, and Central India and Punjab groups were greater. Compared, however, with the average mortality ratios of the 20 years, 1860–79, the ratios of 1884 are in all cases lower. In the Punjab group the death-rate of the year under review was 13·53 per 1,000 less than the 20 years' average. In the Lower Bengal group 12·87, in the Gangetic Provinces 10·31, in the Hill Stations 7·14, in the Meerut 6·19, and in the Agra and Central India group 13·82 below the same averages. In all groups, with the exception of the Hill Stations, enteric fever gave rise to the highest proportion of mortality. In the Agra and Central India group the mortality from this cause rose to 7·51 per 1,000. The next highest ratios were recorded in the Meerut (4·19), Gangetic Provinces (3·96), and Lower Bengal (3·18) groups. Excluding the Hill Stations group, all groups returned higher mortality ratios from this cause than during the previous year, and compared with the average mortality during 1870–79, the first four groups show higher ratios, whilst the ratio of the fifth group (Punjab) is almost identical with the average. Apoplexy caused the largest proportion of deaths in the third, fifth, second, and fourth groups in order; hepatitis in the second, fifth, and third groups; respiratory diseases in the third, fifth, and fourth groups. Dysentery caused some mortality in the third and fifth groups, but none in the remaining groups.

Confining attention to those only of the stations in which the average strength exceeded 200, and which were occupied throughout the year, the highest admission-rates were recorded at Delhi (4,828 per 1,000) and Mecan Meer (3,554). At six stations admission-rates exceeded 2,000, and in five they were under 1,000, the smallest ratio having been 828 at Cannanore. The highest mortality among such stations occurred in Quetta (38·00 per 1,000), and Hyderabad in Sind (32·68). In five stations the ratios were between 20 and 30 per 1,000, in 21 between 10 and 20, and in 27 below 10.

During the year 9,244 men of the Bengal Army, or 27·60 per cent. of strength, were located on the hills. The men located in the Hill Stations enjoyed better health than they did during the preceding year, for the admissions among them equalled 1,201 per 1,000 against 1,454 in 1883; the ratio of 1884 is still, however, higher than usual, for the decennial average of 1870–79 was 1,044. The death-rate was remarkably low, namely, 5·91 per 1,000, the lowest on record since 1870.

The health statistics of the troops of the Rajputana, Malwa, Sind, and Aden group were on the whole favourable. Compared with the ratios of the preceding year, the admission and death-rates (1,548 and 12·77 per 1,000 respectively) are higher, but they are both considerably below the decennial averages of 1870–79. Fevers and venereal diseases as usual gave rise to the largest proportion of admissions; the next highest ratios having been for wounds and accidents, abscesses and ulcers, respiratory diseases,

and diarrhœa. The causes of death were enteric fever (2·02), apoplexy and sunstroke (1·79), cholera and hepatitis (each 1·12). The largest stations included in this group are Mhow and Aden. The former recorded an admission-rate of 1,799 and a death-rate of 6·69; the latter 1,167 and 8·51 respectively.

The health statistics of the troops in the Deccan and Nagpur are on the whole favourable. The admission-rate, 1,171, is certainly higher than it was during the previous year (viz., 1,001, the most favourable on record since 1870), but it compares favourably with the average of 1870–79, which is 1,383. The total death-rate was low, namely, 8·83, against a decennial average of 14·14. Venereal diseases caused the largest proportion of admissions, and next malarial fevers. The chief causes of death were enteric fever, hepatitis, remittent and continued fevers. Secunderabad, the largest military cantonment in India, with an average strength of 2,394, and Poona, with an average strength of 1,019, are included in this group. At Secunderabad the admission-rate was 1,077, and at Poona 1,129, the death-rates having been 9·61 and 9·81 respectively.

The admission-rate for the troops included in the Southern India group was 1,059, a favourable ratio compared with the last ten-year average, which is 1,285. The total death-rate was 7·73, one of the lowest on record, and considerably below the decennial average, 13·70. Venereal diseases contributed 358 per 1,000 to the total admission-rate, whilst malarial fevers caused only 99 per 1,000 of admissions. Dysentery and diarrhœa together gave rise to 92 per 1,000 of admissions. Enteric fever, cholera, apoplexy with sunstroke, and hepatitis, each contributed a little over 1 per 1,000 to the total mortality. This group includes seven stations, the largest of which are Bangalore, Bellary, Cannanore, and Madras. At Bangalore, with an average strength of 1,964, the admission-rate was 1,026, and the death-rate 4·07; at Bellary these ratios were 963 and 7·15.

The average strength of the Burma and Pegu group, including four stations, was 1,785. The total admission-rate, 1,190, was higher than usual, the last decennial average having been 1,092, but the death-rate, 7·28, was very favourable, the ten-year average having been 17·32. Venereal diseases, fevers, and bowel complaints gave rise, as usual, to the largest proportion of admissions, whilst bowel complaints, hepatitis, and phthisis pulmonalis contributed most largely to the death-rate. It is noteworthy that enteric fever gave rise to no deaths, though four cases were treated. Rangoon, Toungoo, Thayetmyo, and Port Blair are the four stations included in this group, the last with an average strength only of 140. The highest admission and death-rates were recorded at Rangoon, 1,586 and 12·43 respectively.

The average strength of the men located in the hill stations of Madras and Bombay was 757. Sickness among them prevailed to the usual extent, the admission-rate of the year having been 1,531 compared with 1,594, the decennial average. Mortality among them, however, 5·28 per 1,000, was considerably below the average of the 10 years, which is 15·16.

Throughout the Army of India 150 cases of cholera were treated, or a proportion of 2·7 per 1,000 of strength. Of this number 107 died, or 71·33 per cent. of those attacked. The prevalence of the disease among the European troops was therefore not great, though greater than in the two preceding years, for during 1882 only 98 cases were treated and 82 during 1883. The type of the disease was, however, more virulent, for the per-centage of deaths among those treated exceeded the per-centages of 1882 and 1883, which were 62·24 and 62·20 respectively, whilst the average admission-rate during 1870–79 was 4·7, and the average per-centage of deaths to seizures 69·11. Cholera.

Of the total 150 cases of the disease, no less than 67 occurred in the Bombay Army. The disease was unusually prevalent in this army, the admission-rate per 1,000 of strength having been exactly three times the average ratio during 1870–79, which was 2·1. It has been noted already that the disease broke out chiefly among the troops occupying Southern Afghanistan. Among these troops 49 cases were treated, and of these 39, or 79·59 per cent., proved fatal. The disease among the men serving there was therefore extremely virulent. The average per-centage of deaths to those treated in the Presidency as a whole during 1870–79 was 73·27.

The troops of the Bengal Presidency come next in order of high proportionate attacks. Among them 71 cases occurred, a proportion to strength of 2·1 per 1,000. These numbers are nearly double the corresponding ones of the preceding year, but in that year the disease was remarkably little prevalent. The average admission-rate for the last decade was 5·9. Of those attacked 45 died, a per-centage of 63·38, which is below the average per-centage of 1870–79, namely, 70·26.

Only 12 cases occurred in the Madras Presidency, representing a ratio of 1·1 per 1,000 against an average of 2·9 during 1870–79. Of those attacked 10 died, yielding the very high per-centage of 83·33, the last ten-year average having been 58·49.

Among the troops of the several geographical groups of the Bengal Army the disease was entirely absent from two of the groups, while it was unusually prevalent in one, namely, the Meerut and Rohilkund group. The admission-rate in this group, 8·4 per 1,000, was more than three times as great as the average admission-rate during the last decade, and nearly equalled the average of 1860–69. Thirty-two men were treated, of whom 16 died, equivalent to 50 per cent. The type of the disease was therefore happily not so severe as usual, for the average per-centage of deaths to attacks during 1870–79 was 68·91. During the preceding year this group remained entirely free of the disease. During recent years the Gangetic Provinces have usually suffered more severely than any of the other groups. It is satisfactory, therefore, to note a diminished prevalence of the disease in this group during the year under report. Twenty-eight cases were admitted (4·4 per 1,000), of whom 20 died, or 71·43 per cent. of those attacked. The last-mentioned ratio is unusually high, the decennial average for 1870–79 having been 63·96. In the Agra and Central India group the admission-rate (2·0) was about one-half the decennial average. Eight cases occurred with seven deaths, or 87·50 per cent. of those attacked, against a ten-year average of 72·38. In Bengal Proper the admission-rate (1·6) was almost identical with the last decennial average. It may be noted that this is the third consecutive year during which the troops in the Punjab remained entirely free of the disease.

Small-pox.

Small-pox was less prevalent in the Army as a whole than it was during 1883. Seventy-eight cases in all were treated (1·4 per 1,000 of strength), of whom 8 died (or 0·14 per 1,000). Both these ratios are greater than the decennial averages of 1870–79, which were 0·7 and 0·10 respectively. The per-centage of deaths amongst those treated was 10·26 against 8·57 in 1883, and 14·71 during 1870–79.

The disease was proportionately most prevalent in the Madras Presidency, where 19 cases occurred, or 1·8 per 1,000 of strength, against 0·5 during 1870–79. Of these only one proved fatal. In the Bengal Presidency 51 cases were admitted (1·5 per 1,000 against 0·8 in 1870–79). The cases were distributed as follows: Gangetic Provinces, 33 cases with 4 deaths; Meerut and Rohilkund, 5 cases with no death; Agra and Central India, 4 cases with no death; Punjab, 8 cases with 2 deaths; and Hill Stations, one case with no death. Fifty-five of the whole number of cases occurred during March, April, and May. In the Bombay Presidency only 8 cases with one death were reported.

Fevers.

In the report for 1883 a great diminution in the prevalence of intermittent fevers was noted. Unhappily this has not continued, for during 1884 the admission-rate for the whole Army of India rose from 359 per 1,000 during the preceding year to 487, a ratio which considerably exceeds the average of the last decade, namely, 389. The excess over the decennial average for the Army of India, however, was entirely due to an increased prevalence of these fevers in the Bengal Presidency, for in the Madras and Bombay Presidencies the admission-ratios of the year were below their decennial averages, whilst in Bengal the ratio of 1884 exceeded the average by 198 per 1,000. It is satisfactory, however, to observe that this increased prevalence of the disease was not accompanied by an increased mortality; indeed the total mortality due to these fevers throughout the Army of India, 0·02 (and representing the death of one man), was below that of the previous year, and nearly seven times less than the average mortality of the last decade.

With an increased prevalence of intermittent fevers, as compared with the previous year, it is not surprising to find an increased prevalence also of the continued forms of malarial fever. The admission-rate for these fevers equalled 60 per 1,000 for the Army of India as a whole against 49 in 1883. The last-mentioned ratio was, however, unusually low, and the ratio of 1884 is considerably below the last decennial average, which was 162 per 1,000. The increased prevalence of these fevers, as compared with the preceding year, was mainly due to the greater incidence of the disease upon the Bombay troops.

Enteric fever.

The number of fever cases now regarded as enteric has risen steadily during recent years. During 1883, 429 cases were admitted into hospital, or 7·7 per 1,000 of strength, whilst in the year under report 644 cases, or 11·7 per 1,000 of average strength, were recorded to have occurred throughout the Army of India. In several

former reports the difficulty attending the diagnosis of this fever from continued malarial fevers and the probability that many cases of the latter have been recorded as enteric has been commented upon, and it is needless to repeat these arguments here. In a subsequent paragraph it will be observed that the Surgeon-General, Bombay, in reporting on the prevalence of enteric fever in the Bombay Army, takes the same view and shows that much confusion exists in the diagnosis of this fever. It will suffice here to compare the results of 1884 with those of nine previous years since 1875 and the approximate averages of the 10 years from that time to the year under report (1884) inclusive. In the following table the admission and death-rates per 1,000 of strength for each of these years is set forth, together with the per-centages of deaths among those treated:—

Year.	Ratios per 1,000 of		Died per cent. of those treated.	Year.	Ratios per 1,000 of		Died per cent. of those treated.
	Admissions.	Deaths.			Admissions.	Deaths.	
1884	11·7	2·74	23·45	1878	8·5	3·64	43·01
1883	7·7	2·40	31·00	1877	4·1	1·60	39·49
1882	6·2	2·55	40·90	1876	4·6	1·82	39·77
1881	5·6	2·64	47·26	1875	2·8	1·44	50·60
1880	7·9	3·63	46·17	1875–84	6·7	2·61	39·08
1879	8·0	3·59	45·01				

An examination of these ratios shows (first) that, during the first three years of the decade these fevers were not so prevalent as they are now, and that compared with the admission-rate their fatality was much greater; (second) that during 1878-79-80 there was a marked increase in the prevalence of the disease, and that the fatality of the disease *in comparison with the admission-rates* was diminished; (third) that during 1881 there was a sudden diminution in the prevalence of the disease, coupled with an increased mortality, in the same sense as above (a mortality almost the same in proportion to admissions as occurred in 1875); (fourth) that since 1881 there has been a very rapid increase in the prevalence of the disease, together with a remarkable fall in the fatality of it, for though the admission-rate during 1884 was considerably higher than in any previous year, the per-centage of death among those treated was never so low. Comparing next the ratios for 1884 with the approximate decennial averages, it will be observed that, though the admission-rate during 1884 was nearly double, the proportion of deaths among those attacked was nearly one-half the average.

In the following table the admission and death-rates for enteric fever and other fevers in the three Presidencies are contrasted:—

Period.	Bengal.						Madras.						Bombay.					
	Admissions per 1,000.			Deaths per 1,000.			Admissions per 1,000.			Deaths per 1,000.			Admissions per 1,000.			Deaths per 1,000.

* Including troops on active service and on the march. † Excluding troops in Afghanistan.

Both enteric fever and other fevers were more prevalent in the Bengal Army than in those of Madras and Bombay. The admission-rate for enteric fever in the Bengal Army, namely, 12·6, is more than double the average ratio of the past decade (5·3); but other fevers were also unusually prevalent, for, whilst the admission-ratio for them during 1884 was 682·8, the decennial average was 607·3. The next highest admission-rate for enteric fever was recorded in the Madras Army, namely, 11·4, closely approaching the Bengal ratio, but other fevers in this army were much less prevalent, the admission-rate for them, 166, having been very considerably below the ten-year average, namely, 266·5. In the Bombay Army enteric fever gave rise to nearly three times as many admissions proportionately to strength as the average of the last decade, namely, 9·1, against an average of 3·1. In this as in the Madras Army other fevers were not so prevalent as usual. Looking next to the total

admission and death-rates in the three armies for both enteric and other fevers together, it will be observed that in the Bengal Army alone does the combined admission-ratio of the year under report exceed the decennial average of 1870-79, yet the total combined death-rate, notwithstanding the fact that there were amongst the cases of fever more than twice as many enteric fever cases in proportion to strength, was below the decennial average. In the Madras Army the combined admission-rate was 177·4 against a ten-year average of 270·4, and although the ratio of the year includes nearly three times as many cases of enteric fever as does the decennial average, yet the combined death-rate was 1·67 against 2·04. In the Bombay Army there were nearly three times as many admissions from enteric fever as during 1870-79, and the total death-rate was also greater, namely, 4·19 in 1884 against an average of 2·89.

The following table is introduced to show the fluctuations in the death-rates from enteric and other fevers during the years 1871-1884 :—

Presidencies.	Fevers.	1871.	1872.	1873.	1874.	1875.	1876.	1877.	1878.	1879.	1880.	1881.*	1882.	1883.	1884.

* Excluding troops in Afghanistan.

The foregoing tables will, it is hoped, have given an insight into any relationship which may exist between enteric and malarial fevers. Their main results are brought together in the following table for facility of comparison :—

Mortality from Enteric Fever and other Fevers.

	During 1870-79.			During 1884.		
	Enteric fever.	Other fevers.	Total of both.	Enteric fever.	Other fevers.	Total of both.
Army of India - - -	2·03	1·42	3·45	2·74	0·64	3·38
„ Bengal - - -	2·28	1·74	4·02	3·31	0·36	3·67
„ Madras - - -	1·42	0·62	2·04	1·67	—	1·67
„ Bombay - - -	1·75	1·14	2·89	2·05	2·14	4·19

The question as to whether all the fevers now so often called enteric are really specifically distinct from malarial fevers, and whether, if this be so, these fevers are specifically the same as the fevers similarly named in Europe will have to be decided upon clinical and pathological data. As far as the indications of statistics may be relied on, they tend to show only that, if the fevers now called enteric are really specifically distinct from malarial fevers, they have always been so, though they have escaped observation, and are probably not to be regarded as a newly introduced disease into India. It was indeed to be expected that a more careful observation of fevers stimulated by the introduction of improved and accessible instruments of research should result in the separation of some of their forms as distinct which were formerly regarded as the same. This view is supported by the results set forth in the above tables, which show that the total mortality from all forms of fever does not on the whole materially differ from what it was 13 years ago, and this is hardly compatible with the view that a new and fatal fever has been recently introduced into India.

The disease again gave rise, as during the preceding year, to the largest number of admissions in Lucknow and Bangalore stations. At Lucknow 55 cases were admitted into hospital, of which 9 proved fatal, against 44 cases and 8 deaths during 1883.

The deaths amongst those attacked were therefore comparatively fewer—16·4 per cent. against 18·2 per cent. in 1883. At Bangalore 60 cases with only one death were recorded against 40 with 14 deaths in 1883. At Secunderabad there were 36 cases and 10 deaths, at Morar 33 cases with 17 deaths, and at Quetta 32 cases with 10 deaths. Over 20 cases were recorded at Sitapur, Meerut, Agra, Mooltan, Rawal Pindi, and Karachi.

The relationship between enteric fever and age is exhibited in the following table:—

Year.	Mortality from Enteric Fever and Ratio of Liability to it at Different Ages.					
	Under 25.		25 to 29.		30 to 34.	
	Deaths per 1,000.	Percentage of liability.	Deaths per 1,000.	Percentage of liability.	Deaths per 1,000.	Percentage of liability.
1877	2·45	44·2	1·55	27·9	0·99	17·8
1878	6·04	53·0	3·55	31·1	2·04	9·1
1879	6·17	54·1	2·73	23·9	1·78	15·6
1880	6·25	56·26	3·15	28·35	1·09	9·81
1881	4·56	59·84	1·57	20·60	0·72	10·37
1882	4·32	56·18	1·55	20·16	0·78	10·14
1883	4·34	66·36	1·50	22·94	0·70	10·70
1884	4·61	62·05	1·83	24·63	—	—

The results given do not differ materially from those of recent years, and their significance has been repeatedly indicated in recent annual reports.

As with age, so with length of service in India, the disease stands in well-defined relationship. With increased service in India liability to become affected by the disease rapidly diminishes:—

Statement showing the proportion of men who have served in India two, five, and seven years from 1871–84.

Period.	Percentage of Men to Total Strength who have served in India.			Period.	Percentage of Men to Total Strength who have served in India.		
	Two Years and under.	Five Years and under.	Seven Years and under.		Two Years and under.	Five Years and under.	Seven Years and under.
1871	36·2	64·6	78·9	1878	28·9	59·8	73·0
1872	33·7	66·7	80·0	1879	32·1	60·9	72·6
1873	31·7	65·5	79·6	1880	33·4	65·4	77·2
1874	25·9	64·3	79·8	1881	38·9	70·4	81·1
1875	26·1	60·1	81·0	1882	33·1	71·9	82·9

1877	25·2	56·2	72·6	1884	36·2	75·0	86·2

Statement showing the death-ratios of the European Army from Enteric Fever at different periods of residence in India, together with Ratios of Liability to it, for 1877–84.

Year.	Mortality from Enteric Fever, and Ratio of Liability to it at Different Periods of Residence in India.					
	1st and 2nd Years.		3rd to 6th Year.		7th to 10th Year.	
	Deaths per 1,000.	Percentage of liability.	Deaths per 1,000.	Percentage of liability.	Deaths per 1,000.	Percentage of liability.
1877	3·34	59·5	1·35	24·2	0·90	16·1
1878	7·90	63·4	2·64	21·2	1·38	11·0
1879	7·99	67·2	2·18	18·3	1·24	10·4
1880	9·08	75·98	1·78	14·90	0·47	3·93
1881	4·55	60·02	2·07	27·31	0·56	7·39
1882	4·68	61·10	1·93	25·19	0·34	4·44
1883	4·98	70·34	1·55	21·89	0·55	7·77
1884	5·47	70·04	1·55	19·85	0·46	5·89

The average strength of the European Army in Bengal Proper is so small that it may be omitted in considering the relationship of enteric fever to season. In all the remaining geographical groups there are two periods of increased incidence of the disease—one April to May, the other August to October. These two periods are most clearly defined in the Punjab and Meerut—Rohilkund groups, where the intensity of incidence is almost equal in the two periods. In the Gangetic Provinces and Oudh group the earlier period of invasion is more marked than the latter, whilst in the Agra and Central India group the reverse obtains, the earlier period being almost obliterated. In all these groups, with the exception of the last-mentioned, namely, Agra and Central India, a tendency to increased activity in the disease manifests itself, though not conspicuously, towards the close of the year.

In the great majority of cases medical officers, in reporting upon the outbreaks of the disease coming under their immediate observations, state that no clue whatever can be found to the causation of the disease in any local insanitary conditions. In most cases the sanitary conditions of the soldiers' surroundings were unexceptionable; for example, at Morar, where in one regiment 33 men were admitted, of whom 17 died, the Medical Officer writes:—"The disease generally was of a bad type, and the "patients were greatly handicapped by the oppressive nature of the weather in "August and September, and I may also add in May and June, for I find that "four deaths occurred during these two months when the heat was very great. I can "in no other way account for the high mortality." The average age of the men attacked at Morar was 23·24. Eighteen cases occurred in men who had been a year or less in India. The average length of residence in India of the men attacked was two years and two months. Nearly every barrack furnished one or more cases. The Medical Officer continues:—"I cannot offer any satisfactory explanation of the cause of the "outbreak. Careful inspection of the barracks and vicinity failed at any time to "reveal more than a few trifling sanitary defects. The milk supply of the troops was "carefully inquired into. It was thought that stable litter might have been used to "feed the cows with, but I made several minute personal inspections of the village, "where all the cows which provide milk for the troops are obliged to be kept under "supervision, and I always found the cow-sheds clean, and that the cows were well "looked after and fed on clean grass and *kerbi*. In the Norfolk Regiment in the same "station (in which 26 cases occurred), milk was not allowed to be hawked about in "vessels for sale, but the cows were driven about the barracks and milked direct into "the vessels of the men. In the absence, therefore, of insanitary conditions I can only "assign the occurrence of so many cases of enteric fever in Morar during 1884 to "climatic causes and to individual susceptibility." Again at Lucknow, where 53 cases were treated, with nine deaths, the Medical Officer writes:—"The source of the "disease could not be ascertained in any of these cases. The sanitary condition of "the barracks and the vicinity was always in excellent order, the water-supply was "very good, and the filters were well attended to." At Sitapur, where 24 cases with four deaths occurred, we have a striking example of difference of opinion in the diagnosis of the disease. The Medical Officer apparently regarded only about one-half of the cases as enteric, but his successor differing in opinion writes:—"In the weekly "returns only 13 cases were shown as enteric fever; but as I had reason to believe "that the diagnosis was incorrect in 11 other cases returned as simple continued "fever, I have made the necessary correction in the annual return." This Medical Officer attributes the disease to the use of porous vessels in latrines. He continues—"On the 19th April, I find I made the following entry in the diary:—Of four admis-"sions from enteric fever during the past week, three men belong to 'G' Company "and came from No. 4 single-storied barrack; other cases of fever and of tonsillitis, "or sore-throat, have also recently been admitted from the same barrack. I made a "close inspection of this barrack and all its surroundings. I not only found that 'G' "Company was the most exposed to latrine air, but that the latrine of the guard-room "was the most conserved throughout the barracks. I consequently came to the "conclusion that it was in the latrines I must look for the cause of the sickness. The "latrines had generally the appearance of being well attended to, and were always "reported to be in 'satisfactory condition': but I always perceived a stench in them "which could not be accounted for by want of ventilation. I discovered that this "was due to the privy-pans, which being of unglazed earthenware, somewhat similar "to common Indian flower-pots, and very pervious, had become saturated with "excrement, now as the weather had become hot, in a decomposing state. I there-"fore attributed the occurrence of enteric fever to the air having become polluted

" with decomposing excrement. I think I should here state that the pans referred " to had been brushed over with a coating of varnish by the contractor or his agent, " and thus passed for the proper glazed earthenware pans. This had been done for " several years, and the last regiment, fresh from home, naturally imagined that the " previous corps had the correct article, and continued to receive it. I would also " here remark that, after the proper glazed earthenware pans were supplied, the latrines " became perfectly free from stench—in fact from any smell; the health of the troops " improved; there were no more admissions for enteric fever; and a very considerable " decrease in the number of admissions for diseases of the digestive system." At Roorkee the Medical Officer in charge of the station hospital states that all the four cases which occurred during the year, as well as all those which occurred during the previous three years, came from the same end of the infantry barracks. He writes— " but the causative agency has not been traced in any of the cases. The buildings " at this end of the barracks are in every respect the same as at the other, and " the food, water, and other supplies for the residents are obtained from the same " sources."

In commenting on the much greater prevalence of enteric fever in the Madras Army during 1884 than in any previous year, and the concomitant reduction in the mortality amongst those attacked, the Surgeon-General, Madras, writes:—"This is probably " accounted for by the fact that executive medical officers have become more careful " in their diagnosis, and that cases are now included under the head of enteric fever " which were formerly returned under the headings of simple continued or remittent " fevers." This is the alternative view to that taken in several previous annual reports of the Sanitary Commissioner with the Government of India, viz., that the increasing admission-ratios for this fever are due rather to a hesitating or timid diagnosis by which many cases of malarial fever of more than ordinary severity are entered in returns as enteric. The reasons for preferring this latter alternative opinion have been given from time to time in former reports as well as in a previous paragraph of this report. The well-established fact that these fevers are almost exclusively confined to the young unacclimatised soldier, and that its seasonal prevalence coincides with the season of greatest prevalence of ordinary malarial fevers, lends support to the view here taken. In the Madras Army, of the 129 cases which were admitted into hospital, no less than 65, or almost exactly one-half, occurred during the months of July, August, and September, the period during which other fevers are most prevalent, for, of the 1,790 admissions for other fevers made during the year, 567, or a little more than one-third, were made during these months. The result is even more striking if we confine attention to the stations in which the disease was most prevalent, viz., Bangalore, Secunderabad, and Kamptee. In these three stations 109 of the whole number of enteric fever cases occurred. Sixty-three of the 109 cases of enteric fever occurred during the months of July, August, and September, and 343 of the 902 cases of other fevers occurred during the same months, or about one-third of the whole. In connexion with this subject it is interesting to note that, amongst the Native troops serving in Bangalore and Secunderabad, only three cases of enteric fever were treated during the year.

The Surgeon-General, Bombay, in reporting on the prevalence of enteric fever amongst British troops in that command during 1884 takes a different view from that of the Surgeon-General, Madras, and one that coincides in most respects with the view supported in these annual reports for several preceding years. He is of opinion that "there is a form of fever called enteric fever which is not that disease *proper*, " but which is due to *malaria*, and presents great difficulties in diagnosis from true " enteric fever"; and secondly, that "we have pure enteric fever which he believes " might almost invariably be traced to pre-existing causes if our information were " complete." Throughout the Bombay Army 98 admissions were made for enteric fever with 22 deaths, or equivalent to very nearly one death in 4·5 cases. The disease was specially prevalent in Quetta and Karachi, in which stations 30 and 28 admissions respectively were made. The greatest number of cases occurred during July, August, and September. The disproportion in the ratio of deaths to cases treated at different stations is very noticeable, "for," as the Surgeon-General writes, "whilst Ahmednagar " shows a series of 10 cases without one death, Quetta shows a mortality which almost " approaches that of cholera, viz., one death in every three cases; Karachi shows, on " the other hand, a mortality of only 1 in 9." With regard to the outbreak at Quetta, it is noted that sickness generally was unusually prevalent during the latter half of the year, and all the cases of enteric fever were admitted during this time.

In the marginal table the admissions for all diseases at Quetta, and an analysis of them showing the share taken by fevers of all kinds in them during the latter half of the year, are given. In regard to these figures the Surgeon-General writes:—"It "will be observed that, during what "may be called the four fatal months

Admissions: Quetta.

	Total admissions.	Fevers as whole.	Intermittent fever.	Remittent and continued fevers.	Enteric fever.
June	159	42	23	17	—
July	201	50	19	26	4
August	334	110	59	47	4
September	343	227	88	133	16
October	332	207	161	39	6

"of 1884 in Quetta (July, August, September, and October), those severest forms of "climatic fevers (remittent and continued fevers) were far more prevalent than the "milder intermittents; it will also be seen that, during these four months, all the "enteric cases occurred. It is also worthy of note that, during the month of "September, when remittent and continued fevers were rampant, half the cases of "enteric fever occurred." In connexion with this outbreak the difficulties attending the diagnosis of true enteric fever from malarial fevers of a continued type are set forth as follows:—"That difficulties in diagnosis presented themselves to the medical "officers at Quetta is abundantly shown in my last quotation from the reports of "Dr. Bradshaw, wherein the officer in charge of the Station Hospital announces that, "for the week ending the 12th September, 7 cases of enteric fever were admitted, "but of these no fewer than 6 were 'revisions of diagnosis,' *i.e.*, these 6 cases had "been under treatment up to the 5th September for some other disease. Now, of all "the diseases prevailing at Quetta, remittent fever and continued fever of a malarial "character are the fevers which in all probability would present those difficulties in "diagnosis from enteric fever to which I have referred. If we remember that enteric "fever is a continued fever of long duration, and that it has always been regarded "*per se* as distinctly non-malarial, may we not hesitate in pronouncing all those "30 cases which occurred at Quetta as enteric fever? Especially do I consider it "doubtful, seeing how we have noted that, in one week, 6 of those cases were revisions "of diagnosis, these having been presumably originally treated as either remittent or "malarial continued fever."

After fully considering the outbreak in the Quetta district, he says that he is of "opinion that many of the cases were possibly aggravated forms of continued or remittent fevers which in their progress assumed 'typhoid' character."

Bowel complaints.

Dysentery was somewhat more prevalent in the army as a whole than during the preceding year, the admission-rate having been 29 against 27 per 1,000; but the former ratio is considerably under the average of the last decade, namely, 40. Diarrhœa gave rise to an admission-rate of 50 per 1,000 against a decennial average of 63 per 1,000. The severity of the cases of dysentery treated was not so great as during the previous year, for the per-centage of deaths to those treated was 1·31 against 1·40 in 1883 and 3·65 during 1870–79. Diarrhœa was of a severer type, the per-centage of deaths having been 1·08 against 0·08 in 1883 and 0·19 the average of the last ten-year period. Dysentery was most prevalent as usual in the Madras Army, but it caused the largest proportion of deaths to strength in the Bombay Army. Diarhœa, on the other hand, was more prevalent in the Bengal and Bombay armies.

Apoplexy.

Apoplexy and sunstroke gave rise to an admission-rate equal to that of the preceding year, namely, 3 per 1,000, and to an almost identical death-rate, namely, 1·09 against 1·10.

Hepatitis.

There was some reduction in the admission-rate for hepatitis in the army as a whole compared with the preceding year (26 per 1,000 against 29 in 1883), a reduction shared in by each of the three Presidential armies, but especially by the Madras and Bombay armies. The mortality caused by this affection in the army as a whole was almost exactly one-half the average mortality of the last decade, namely, 1·11 against 2·19. This total reduction was mainly due to the diminished mortality in the Bengal and Madras armies whose death-ratios for the year under review are 1·20 and 1·12 per 1,000 below their respective ten-year averages, whilst in the Bombay Army this difference amounts to only 0·68. Of the several groups into which the Bengal Army has been divided, this disease caused the largest admission-rates in the Meerut and Rohilkund group (33 per 1,000), Agra and Central India group (28), and Gangetic Provinces (27).

ype of disease was most severe in the Gangetic Provinces, where 4·68 per cent. of hose treated died; next in the Punjab, where this per-centage was 3·37. It was least atal in Agra and Central India, where only 0·89 per cent. died. Of the remaining roups of the Army of India, the Burma with Pegu and Southern India groups yielded igh admission-rates, viz., 37 and 33 respectively, whilst the highest per-centages of eaths to those attacked were recorded in Southern Afghanistan (8·33 per cent.), Deccan (7·64), and Rajputana, &c. (7·46).

Respiratory diseases.

It is satisfactory to observe that the rise in the admission-rate from respiratory liseases in the Army of India as a whole, which was noted in the report for 1883, has ot continued. The admission-rate for the year under report, namely, 78 per 1,000, is 2 per 1,000 below the average of the last decade. The total mortality due to these liseases, namely, 0·73 per 1,000, though less than the last decennial average, was omewhat greater than the ratio of 1883.

The Bombay Army recorded the highest ratios both as regards admissions and deaths. This is mainly attributable to the high ratios prevalent in the portion of the Bombay Army located in Southern Afghanistan. In this section of the Bombay Army the dmission and death-rates were 165 and 6·25 respectively against 82 and 1·40, the orresponning ratios of the Bombay Army as a whole. Of the various sections of he Bengal Army, excluding hill stations, the highest admission-rates occurred in the Punjab (88 per 1,000), and Meerut and Rohilkund (81 per 1,000), whilst the lowest vere recorded in Bengal Proper (37 per 1,000), and Gangetic Provinces with Oudh 70 per 1,000). Comparing the ratios of admission during the year under report with he ten-year averages of 1870–79, it will be seen that, whilst in the Bengal and Madras Armies those of the year are below the averages, in Bombay the ratio of 1884 xceeds the average by 18 per 1,000. The same excess of the present year's result ver the last ten-year average is observable in the mortality due to these diseases in he Bombay Army, namely, an excess of 0·70 per 1,000, whilst in the two other armies he results of 1884 are below the average.

Venereal disease in Army of India as a whole.

In the report for 1883 it was noted that the admission-rates for these diseases in the European Army of India had steadily risen. The result of another year's experience dds unfortunately to the progressive series of increased admission-rates, for during 884 it was 294 per 1,000 against 270 in 1883, and 203 the average of 1870–79; and his rise in admission-rate for the army as a whole was shared in by each of the three residential armies, most largely by that of Bombay.

Admissions from Venereal Diseases in the three Presidencies,

Presidency.	Admissions per 1,000.						
	1860–69.	1870–79.	1880.	1881.	1882.	1883.	1884.
Bengal - -	265	209	276*	276*	271	281	291
Madras - - -	†	198	275	258	288	289	307
Bombay - -	†	194	269	261*	224	218	292
India - -	†	203	250	260	265	270	294

* Excluding troops in Afghanistan.
† The statistics of Madras and Bombay, and for the whole of India for these years are not available.

Primary and secondary syphilis gave rise to a larger proportion of admissions in the Madras Army than in the other two Presidencies, but gonorrhœa was more prevalent in he Bengal and Bombay armies than in that of Madras. Gonorrhœa was unusually prevalent in all three armies. In the following table the admission ratios for syphilis nd gonorrhœa in the three armies of India are compared with those of 1872:—

	Primary Syphilis.			Secondary Syphilis.			Gonorrhœa.		
	1884.	1872.	Difference.	1884.	1872.	Difference.	1884.	1872.	Difference.
Bengal Army -	86·7	61·9	+24·8	25·3	22·6	+2·7	147·5	87·2	+60·3
Madras „ -	101·7	65·4	+36·3	26·3	29·2	−2·9	135·8	61·5	+74·3
Bombay „ - -	89·7	54·4	+35·3	19·9	14·0	+5·9	142·3	75·7	+66·6

It will be seen that the results of the present year are in all cases with the single exception of secondary syphilis in the Madras Army less favourable, and often very considerably less favourable, than those of 1872.

Invaliding.

Throughout the Army of India, 1,757 men were invalided, or 31·74 per 1,000 of strength. This ratio is below those of the three preceding years, and 11·30 per 1,000 below the last decennial average. It is the second lowest ratio on record since 1870, the lowest having been 26·31 in 1880. The proportions of invalids contributed by the three Presidencies were remarkably even, differing from one another fractionally between 31 and 32 per 1,000.

Forty-one per cent. of the total number of men invalided in the Army of India were discharged as unfit for further service. This is a larger proportion than usual. The excess of invaliding for discharge over that for the previous year was due entirely to the greater numbers thus invalided from the Bombay Army, for in the Bengal Army the ratio was the same and in the Madras Army lower. The largest proportion of invaliding for discharge took place in the Bengal Army, and the least in the Bombay Army, the Madras Army being intermediate. The chief cause in each Presidency was as usual anæmia and debility. These give rise to an invaliding ratio of 4·03 in the Bengal Army, 7·88 in the Madras, and 7·84 in the Bombay Army. In the Bengal and Madras armies the next most prolific cause of invaliding was hepatitis 3·32 and 2·69 respectively. In the Bombay Army this ratio was only 1·66 per 1,000, whilst phthisis pulmonalis gave rise to the second highest invaliding ratio, namely, 3·14.

Invaliding due to mental diseases was noticed for the first time in the report for 1883, as the subject was one to which attention had been specially called. There is nothing further to note regarding this cause of loss to the army beyond what is there stated. It will suffice, therefore, to add the figures of 1884 to those already given in the following table:—

Total Cases of Mental Diseases.

Year.	Bengal.	Madras.	Bombay.	India.	Year.	Bengal.	Madras.	Bombay.	India.
1877 -	44	14	11	69	1881 -	39	18	18	75
1878 -	40	8	8	56	1882 -	48	15	14	77
1879 -	51	16	6	73	1883 -	54	19	13	86
1880 -	39	7	6	52	1884 -	58	18	12	88

In regard to invaliding with reference to age the per-centage of those under 25 years to whole number invalided was 38·70 throughout the Army of India. This is larger than that of the preceding year, namely, 36·55, which was itself unusually high. But the number of those invalided between 25 and 34 was smaller than in 1883, whilst for those from 35 years of age and upwards the ratio of 1884, namely, 17·64, was greater again than the ratio of 1883, which was 15·41. As regards the influence of length of service in India upon invaliding, a residence of from two to five years is the time during which the largest proportion of men break down. The per-centage of men under two years' service to the whole number invalided was considerably higher than during the two previous years (24·19 against 19·84 in 1883, and 17·35 in 1882); but this was more than compensated for by the reduction in the per-centage of men between two to five years invalided (49·97 against 57·81 in 1883, and 57·30 in 1882. The per-centage of men in the Army of India up to five years' residence during 1884 was 75, the same as in 1883, as against 72 in 1882. With gradual increase in the number of men of such service there was a corresponding increase in the proportion of men of that service invalided up to 1883. The result of 1884 shows a sudden check to this rising series of per-centages invalided, for whilst the army contained 75 per cent. of men under five years' service, the same as in 1883, yet the proportion invalided fell from 76·75 in 1883 to 74·16, nearly the same as it was in 1882 (74·65) when there were only 72 per cent. of such men.

The following table discloses unusual results, for it shows that the health of newly arrived soldiers was, on the whole, better than that of soldiers longer in the country :— Health of newly-arrived regiments.

Experience of newly-arrived Regiments in 1884 (*during their First Year of Indian Residence*).

—	Strength.	Ratio per 1,000 of Strength.							
		Admission-rate.	Daily Sick-rate.	Death-rate.	Deaths from				
					Enteric Fever.	Other Fevers.	Apoplexy.	Dysentery and Diarrhœa.	Hepatitis.
Army generally -	54,996	1513·4	67·0	12·56	2·74	0·64	1·09	0·47	1·11
New regiments -	3,861	1341·6	62·2	10·88	2·33	1·81	1·30	—	0·48

Both in respect of sickness and in mortality the ratios of newly-arrived regiments were more favourable than those of the army generally. In most years the reverse is the case, and in the report for the preceding year it will be seen that the admission and daily sick ratios of newly-arrived regiments were considerably in excess of the general rates, whilst the death-rate exceeded the general mortality of the army by 9·08 per 1,000. During 1883, however, a larger mortality among newly-arrived soldiers was attributed to enteric fever, namely, 8·95 per 1,000, whilst in 1884 only 2·33 of the total mortality was contributed by the same disease.

For the first time since 1875, a continuous decline in the numbers of women and children in the European Army of India has been checked. The rise in the number of women is, however, small; that in the number of children more considerable. The number of women was 3,371, among whom 59 deaths occurred, equivalent to 17·50 per 1,000, a favourable average, both as compared with that of the preceding year and the average of 1870–79, which was 25·09. Child-birth and abortion gave rise to the largest proportion of deaths, viz., to 2·97 per 1,000, almost identical with the average mortality from those causes during 1870–79, which was 2·93. The next most frequent causes of death were phthisis and apoplexy with sunstroke, which each gave rise to a mortality ratio of 1·78. Enteric fever gave rise to five deaths against three in 1883. Enteric fever, malarial fevers, apoplexy with sunstroke and respiratory diseases alone of the chief causes of mortality gave rise to higher death-rates than in 1883. The women of the Bengal Presidency suffered a considerably higher mortality than those of the Madras and Bombay Presidencies, the total death-rates being Bengal 22·53, Madras 10·56, and Bombay 12·21. Child-birth and abortion were the causes of greatest mortality in all three Presidencies. Sickness and mortality among women and children.

In the Army of India there were on an average 6,453 children. Among these 354 deaths occurred, equivalent to 54·86 per 1,000, a higher ratio than that of the preceding year (46·88), but below the average of the preceding ten-year period 1870–79, namely, 68·96. Diarrhœa was the most frequent cause of death, giving rise to a mortality of 11·47 against 8·48 in 1883. Convulsions came next with a mortality of 9·61 against 8·31 in 1883. Bronchitis and pneumonia also gave rise to a larger proportion of deaths than in 1883, namely, to 5·89 against 3·66, whilst anæmia and debility, dentition, and tabes mesenterica caused a smaller proportion of deaths. Measles appears to have been unusually prevalent, giving rise to an admission-rate of 50·4 per 1,000 against 14·0 in 1883 and to a death-rate of 3·72 against 0·33. The distribution of the total mortality among children of the Army of India in the three Presidencies was as follows:—Bengal 65·70, Madras 32·82, Bombay 53·88.

The total number of officers in the whole Army of India amounted to 5,647, of whom 2,718 belonged to the British Army and 2,929 to the Native Army. Among the officers of the British Army 33 deaths occurred, or 10·30 per 1,000, whilst among the officers of the Indian Army 28 deaths were reported, or 8·11 per 1,000. The combined ratio of mortality for both classes of officers together was 9·17. All these ratios are favourable when compared with the preceding three years. Mortality among officers.

Native Troops.

Sickness and mortality in 1884.

The health of the native army of India, as a whole, was very favourable during 1884. Sickness was certainly somewhat more prevalent than in the preceding year, as both the admission and daily sick-rates were greater; but as the mortality from all causes was less, the type of sickness must have been of a less severe character. The admission and daily sick-ratios, 1,042 and 33 per 1,000 respectively, are but little in excess of those of the very favourable year 1877, and they are both below the quinquennial averages of 1877–81. The total mortality-ratio 10·50 is extremely favourable, being the lowest on record since 1877, when the results for the whole army of India were for the first time brought together. This ratio is also below that of the European army of India, namely, 12·56, and is almost a third of the total mortality in the jails of India, which was 29·11. Cholera was but little prevalent among these troops, and but for this the total mortality from all causes would not have been so favourable as that of 1877, for omitting the deaths due to this cause from both years, the result of 1877 would be fractionally more favourable than that of the year under report.

Sickness and Mortality during the years 1877 *to* 1884 *compared.*

Year.	Average Strength.	Ratio per 1,000.				Mortality, including absent Deaths.
		Admissions into Hospital.	Daily Sick.	Deaths from		
				Cholera.	All Causes.	
1877–81	118,669	1,422	48	1·94	24·90	27·40
1877	113,966	1,030	32	1·53	10·90	13·38
1878	117,273	1,460	43	2·06	18·04	21·02
1879	121,107	1,735	58	4·61	35·15	37·79
1880	126,385	1,545	56	0·53	39·22	41·12
1881	114,612	1,305	46	0·97	19·24	22·62
1882	114,894	1,129	37	1·02	12·24	14·76
1883	114,830	923	31	1·15	11·76	14·31
1884	114,827	1,042	33	0·71	10·50	12·22

Malarial fevers were of course the most usual causes of admission into hospital, giving rise to 503·2 per 1,000 of admissions against 387·4 in 1883. Compared with the preceding year almost all the chief causes of admission gave rise to higher ratios; but cholera, small-pox, venereal diseases, abscesses with ulcers and wounds with accidents gave rise to somewhat smaller ratios. Bowel complaints and respiratory diseases were less prevalent than usual, although somewhat more so than during 1883. Enteric fever gave rise to the same proportionate number of admissions as during the past three years, but the disease was much more fatal, for of those treated 61·11 per cent. died. During 1883 the per-centage of deaths among those attacked was the lowest on record since 1877, and the next highest ratio to that of the year under report was 58·33 in 1882. In actual numbers these ratios mean that of 18 patients treated during 1884, 11 died. The chief cause of mortality in the native army is usually respiratory disease, and during 1884 it caused 2·97 per 1,000 of the total mortality. This ratio is below the average of late years, which, however, was unduly raised by the high ratios which prevailed during 1879 and 1880, years of active warfare. Next to respiratory diseases fevers contributed most largely to mortality (1·80 per 1,000), and next in order cholera (0·71), dysentery (0·70), phthisis (0·64), and diarrhœa (0·44).

Bengal Army.

Sickness in the Bengal Army was less prevalent than usual. The admission-ratio, 1,193 per 1,000, is considerably greater than it was during 1883, but the ratio of that year was unusually low. In the following table it will be observed that the ratio of 1884 is less than the last decennial average, 1,360. The daily average sick-ratio, 35 per 1,000, is not unfavourable:—

Year.	Average Strength.	Ratio per 1,000.				Mortality, including absent Deaths.
		Admissions into Hospital.	Daily Sick.	Deaths from		
				Cholera.	All Causes.	
1867–76	39,508	1,360	42	2·12	13·84	17·25
1877	39,649	1,097	34	0·35	10·32	13·63
1878	41,116	1,645	49	2·09	22·59	25·57
1879*	31,116	2,023	68	2·80	31·78	53·61‡
1880*	30,365	1,609	65	1·52	33·85	53·15‡
1881*	36,899	1,495	51	0·92	19·76	27·93†
1882	40,256	1,250	41	0·72	13·34	16·49
1883	40,932	985	32	0·56	10·55	13·98
1884	40,850	1,193	35	0·71	10·97	12·56

* Excluding troops in Afghanistan.
† These ratios are calculated on the total regimental strength, including the army in Afghanistan.

Although sickness was more prevalent than in 1883, the total mortality from all causes did not rise proportionately but remained almost as low as the favourable ratio of that year. Bowel complaints were considerably more prevalent than in 1883, the ratios of admissions having been 99·1 and 67·0 respectively, but abscesses and ulcers gave rise to a diminished admission-ratio, namely, 96·5 against 114·0. Fevers gave rise to a higher mortality than in the preceding year, namely, to 2·40 per 1,000 against 1·62. Dysentery, cholera, anæmia, and wounds and accidents also contributed more largely to mortality than in the preceding year. Of cholera, 41 cases were treated, of which 29, or 70·73 per cent., terminated fatally.

The proportions in which the various geographical sections of the army contributed to the general admission and death-rate are shown in the following table:—

Year.	Ratio per 1,000.									
	Bengal Proper and Assam.		Gangetic Provinces.		Rohilkund and Meerut.		Agra and Central India.		Punjab.	
	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.
1867–76	1,523	19·13	1,062	8·38	987	11·19	1,588	9·61	1,459	14·24
1877	1,492	19·64	768	5·19	942	9·52	906	7·41	1,243	8·85
1878	1,527	22·13	1,036	7·88	1,008	9·83	1,581	12·96	1,896	18·33
1879	1,816	25·57	1,658	11·05	2,038	36·17	2,303	16·07	2,173	47·64
1880	1,757	40·63	1,222	20·50	1,395	24·46	1,884	28·52	1,687	38·02
1881	1,772	22·53	1,260	15·78	1,378	15·67	1,380	9·35	1,521	22·86
1882	1,569	18·22	1,081	10·01	1,683	9·98	1,248	7·18	1,268	13·30
1883	1,408	16·23	970	8·17	978	11·53	906	5·77	830	10·80
1884	1,367	14·61	929	6·00	1,188	10·62	1,312	7·84	1,083	8·49

Sickness was most prevalent in Bengal and Assam and Agra and Central India and least prevalent in the Gangetic Provinces and Punjab. In all groups excepting the Rohilkund and Meerut the admission-ratios of the year are below the averages of 1867–76. The ratios in the last-mentioned group have been above the decennial average since 1878, with the single exception of 1883. As regards mortality, the most favourable results were recorded in the Gangetic Provinces and Agra and Central India groups and the worst in Bengal and Assam. In all groups the ratios of 1884 are below the averages of the last decade.

The chief causes of sickness in the various geographical groups are set forth in the following table:—

Groups.	Ratio of Admissions per 1,000 of Strength.					
	Fevers.	Bowel Complaints.	Spleen Diseases.	Respiratory Diseases.	Rheumatism.	Abscess and Ulcer.
Lower Bengal and Assam	593	204	11	75	55	80
Gangetic Provinces	346	63	8	48	46	120
Rohilkund and Meerut	530	69	17	46	39	101
Agra and Central India	836	56	8	45	33	95
Punjab	629	49	8	44	27	87

Compared with the ratios of 1883 fevers were more prevalent in every group except the Bengal-Assam group. The excess was slight in the Gangetic Provinces, and Rohilkund—Meerut groups, but was considerable in the Agra—Central India and Punjab groups. Bowel complaints gave rise to higher ratios in every group but especially in the Bengal-Assam, Rohilkund—Meerut and Agra—Central India groups. Spleen diseases were less prevalent only in the Punjab group; in the Rohilkund—Meerut group the ratio is almost six times greater than in 1883, when it was only 3 per 1,000. Respiratory diseases were, on the whole, prevalent to the same extent as in 1883; in Rohilkund—Meerut the ratio of 1884 exceeded the ratio of the preceding year most, namely, by 8 per 1,000. Rheumatism was more prevalent in Bengal-Assam and Rohilkund—Meerut and less prevalent in Gangetic Provinces and Punjab. Abscesses and ulcers were less prevalent in all groups except the first, where the excess in the admission-rate was but nominal, 1 per 1,000.

The chief causes of mortality in the several geographical groups in the Bengal Army are shown in the following table:—

Groups.	Ratio per 1,000.				
	Cholera.	Fevers.	Bowel Complaints.	Respiratory Diseases.	Total.
Lower Bengal and Assam	1·76	2·99	2·11	2·11	14·61
Gangetic Provinces	0·67	1·07	—	1·74	6·00
Rohilkund and Meerut	0·49	2·51	0·97	1·93	10·62
Agra and Central India	1·06	2·12	1·06	0·35	7·84
Punjab	—	2·31	0·75	2·78	8·49

Cholera gave rise to a somewhat smaller ratio of mortality in the first group than in 1883, but in the Gangetic Provinces and Rohilkund—Meerut groups the reduction over the previous year's ratios was pronounced. In the Punjab there was no mortality from cholera, and in the preceding year only one death was registered from this cause. The Agra—Central India group registered a mortality of 1·06 per 1,000 against none in the two preceding years. Fevers were less fatal in the second group than in 1883, but the reduction in the present year's ratio was slight. In the remaining groups the ratios were higher, and the excess in the case of the Agra—Central India and Punjab groups was pronounced, as the ratios of 1883 were 0·99 and 0·79, respectively, against 2·12 and 2·31 in 1884. Bowel complaints were more fatal in the Rohilkund—Meerut and Agra—Central India groups than in 1883, but in the Bengal-Assam and Gangetic Provinces they were less so, whilst the mortality-ratio in the Punjab was much the same. It is satisfactory to note that respiratory diseases gave rise to smaller mortality-ratios in every group, but specially in the Punjab, where the ratio of 1884 was about one-half that of 1883.

Of the stations occupied throughout the year, only one, Dhuki and Gumbuz, with an average strength of 278 men, recorded an admission-rate above 2,000 per 1,000. Twelve stations recorded rates varying from 1,500 to 2,000 against only five in 1883; Baxa, Banda, Delhi, Mooltan, and Mecan Meer were prominent among these, all with ratios exceeding 1,700 per 1,000.

Five stations occupied throughout the year by the regular troops of the Bengal Army recorded mortalities exceeding 20 per 1,000 against 4 in 1883. The stations are, Dhuki and Gumbuz 68·35, Dibrugarh 25·71, Dehra Dun 25·27, Alipore and Baliganj 24·24, Shillong and outposts 21·08.

In Dehra Dun the average strength was 554, and 14 deaths gave rise to the ratio quoted; four of these were due to fevers and four to phthisis. At Dibrugarh the average strength was 739 and 19 deaths occurred; four due to fevers and two to each of the following—dysentery, respiratory diseases, phthisis, and anæmia. At Alipore and Baliganj, out of a strength of 825, 20 deaths took place; cholera, intermittent fevers, and respiratory diseases caused three each, and remittent and continued fevers, dysentery, and diarrhœa each two. At Shillong there was an average strength of 664 men and 14 men died; cholera caused three and diarrhœa and phthisis each two deaths.

Thirteen regiments or detachments of the regular army of Bengal suffered a mortality exceeding 20 per 1,000, and of them five were serving in Bengal, Assam and Bhootan, and four in Southern Afghanistan. The 12th Bengal Infantry at

Cachar and its outposts recorded a mortality of 30·23 per 1,000. This regiment arrived in 1881 from Agra. Twenty-four men died. The 42nd Bengal Infantry at Dibrugarh and its outposts, a local regiment, which arrived at this station from the Naga Hills in January 1883, suffered a loss of 25 men, or 29·52 per 1,000. Only one regiment in the Rohilkund and Meerut group comes under this category, namely, the 22nd Bengal Infantry at Delhi; but it arrived there in the course of the year from Meean Meer. It lost 17 men, equivalent to 20·91 per 1,000. Five of the deaths of men present with their regiments were due to fevers and eight to pneumonia and pleurisy. In the Agra and Central India group one regiment, the 40th Native Infantry at Jhansi, lost 18 men, or 22 per 1,000. It arrived at this station in December 1883, from Barrackpore. Three deaths were from cholera and six from fevers. Among the regiments in the Punjab, the 45th Rattray's Sikhs at Jhelum (head-quarters in Southern Afghanistan for half the year), and the 1st Native Infantry (head-quarters, for 3½ months in Afghanistan) are the only regiments with a mortality exceeding 20 per 1,000. The former lost 18 men and the latter 22 (13 from pneumonia and pleurisy). Of the regiments in Southern Afghanistan, the 10th Bengal Cavalry lost 15 men, equivalent to 27·83 of strength. A detachment of Sappers and Miners lost 30 men, equivalent to 66·52 per 1,000 of strength. Fevers, respiratory diseases, and bowel complaints were the principal causes.

The health of the Punjab Frontier Force was very favourable. Admission, daily sick, and death rates were all the lowest on record since 1877. More than one-half of the total admission-ratio was contributed by fevers. It is satisfactory to note a considerable reduction in the admission-rate for respiratory diseases, which was 72 per 1,000 against 109 in 1883. The ratio of 1884 is still, however, above the average of 1867–76 which was 66. The actual number of deaths from respiratory diseases was 54, equivalent to 5·16 per 1,000 of the average strength of the force, viz. 10,458, against 148, or 14·18 in 1883. The largest number of admissions were made in Dera Ismail Khan (1,572) and the lowest in Abbottabad (748). The highest mortality was recorded in Dera Ghazi Khan (20·05), the lowest in Abbottabad (5·63). Of individual regiments in this force, the 4th Punjab Infantry at Dera Ghazi Khan (head-quarters for three months on the Zhob Valley expedition) suffered the largest mortality, namely, 26·96 per 1,000. This represents 22 deaths, seven of which among those present at head-quarters were due to pneumonia and pleurisy. The 5th Punjab Infantry at Dera Ismail Khan also suffered a high mortality ratio, viz., 20·99, representing 17 deaths. Next come the 3rd Punjab Cavalry at Rajanpur with 10 deaths and the 3rd Sikh Infantry at Kohat with 15 deaths.

The health of the Central India regiments during the year under report was very favourable in every respect, but especially in the small death-rate of 7·23 per 1,000 of an average strength of 5,082. Thirty deaths occurred in all, 12 of which were due to respiratory diseases. Judging from the admission-ratios in the several stations occupied by these regiments, Kherwarah and Erinpoorah were the most unhealthy, each with ratios above 900 per 1,000, and Goona and Deoli the most healthy. The highest death-rate was recorded in Agar (10·36) and the lowest in Kherwarah (1·62). The Mhairwarra Battalion at Ajmere suffered the greatest mortality, 11·13, representing eight deaths, four of which among those present with their regiments were due to pneumonia and pleurisy. The 1st Central India Horse lost five men (10·22 per 1,000). The Meywar Bheel Corps at Kherwarah lost only one man from pneumonia out of those present with their regiments.

The health of the troops of the Hyderabad Contingent is usually extremely favourable, and during 1884 the vital statistics of the force maintained their favourable character. There were in all 32 deaths (4·56 per 1,000 of average strength of 7,014), two of which were due to cholera. The admission-rate was highest in Jaina (928) and Ellichpur (785), and lowest in Bolarum (250) and Raichore (380). The 5th Infantry at Ellichpur lost six men and the 4th Infantry at Bolarum seven men, whilst the 3rd Cavalry, 2nd Cavalry, and No. 1 Field Battery lost one each. The 2nd and 4th Field Batteries and the 1st Cavalry lost none.

Madras Army.

The health of the Madras troops was on the whole very favourable. The admission and death-rates were among the most favourable on record. Cholera gave rise to 80 admissions against 173 in 1883. Of the former number 41 died, equivalent to 51·25 per cent. of those attacked against a ratio of 46·82 in the preceding year. Small-pox gave rise to 100 admissions, of which six only proved fatal. The corresponding numbers of the preceding year were 77 and 4.

Sickness and Mortality during the last Eight Years compared.

Year.	Average Strength.	Ratio per 1,000.				Mortality, including absent Deaths.
		Admissions into Hospital.	Daily Sick.	Deaths from		
				Cholera.	All Causes.	
1877	23,304	861	28	2·79	11·80	14·36
1878	25,728	841	29	2·23	12·25	15·49
1879	27,314	1,269	43	3·19	18·89	21·23
1880	28,710	1,399	54	0·10	15·57	19·54
1881	28,533	997	41	1·37	12·02	16·75
1882	27,654	879	30	2·64	12·01	14·99
1883	27,703	737	27	2·92	10·76	12·51
1884	25,059	836	31	1·46	10·02	11·82

Of the large stations in the Madras Presidency with an average strength exceeding 1,000 men, Secunderabad recorded the highest admission-ratio, namely, 1,416 per 1,000, and next to it Madras (606), Bangalore (520), Bellary (512), Trichinopoly (483), and Kamptee (457). The highest mortality was recorded in Toungoo (22·88), and the next at Secunderabad (18·55). Deaths in Toungoo were due to various causes, but none to cholera; whilst at Secunderabad, of the 64 deaths which gave rise to the above-mentioned ratio, 27 were due to this cause. At Bangalore, where the largest native force is quartered, the total mortality was 6·27, 22 deaths giving rise to it. Of individual regiments the 11th Native Infantry at Secunderabad suffered the largest mortality in proportion to their numbers. This regiment arrived in April from Rangoon and lost in all 34 men, equivalent to 37·99 per 1,000. Thirteen deaths were due to cholera and eight to dysentery and diarrhœa. The 1st Madras Native Infantry also suffered heavily. The regiment was serving in Southern Afghanistan, and was on the march to and at Bangalore for a month and a half of the year. It lost 27 men, equivalent to 33·75 per 1,000 of strength. None of the deaths were due to cholera, but 18 were caused by pneumonia and pleurisy. The 3rd Madras Native Infantry at Toungoo lost 26 men (33·25 per 1,000).

Bombay Army.

The health of the Bombay Army was not so favourable as it had been during the two previous years. Sickness was more prevalent and mortality somewhat greater.

Sickness and Mortality during the last Eight Years compared.

Year.	Average Strength.	Ratio per 1,000.				Mortality, including absent Deaths.
		Admissions into Hospital.	Daily Sick.	Deaths from		
				Cholera.	All Causes.	
1877	23,388	1,074	33	1·93	10·90	12·96
1878	23,672	1,702	45	2·36	15·12	17·95
1879	22,854	1,663	54	3·11	20·22	21·99
1880*	15,328	1,283	45	—	10·44	56·53‡
1881*	18,349	1,166	41	1·85	14·01	25·93‡
1882†	23,772	1,067	36	0·46	12·16	13·41
1883	23,576	994	35	0·47	12·81	14·96
1884	23,373	1,153	38	0·39	12·96	14·35

* Excluding Afghanistan. † Including troops in Southern Afghanistan.
‡ These ratios are calculated on the total regimental strength, including the army in Afghanistan.

Fevers gave rise to a considerably higher admission-ratio than in 1883, viz., to 570 per 1,000 against 399. Respiratory diseases were also more prevalent, but mortality from them was reduced. Bowel complaints were more fatal than in 1883; they gave rise to 40 deaths, equivalent to 1·71 per 1,000 of strength, against 22 deaths, or 0·94, in 1883. It is satisfactory to observe that scurvy gave rise to only four deaths against 14 in 1883.

Sickness was most prevalent in the stations occupied in Southern Afghanistan and the Persian Gulf. At Dhuki, Gundakindoff, and Bolan Pass the admission-rates were between 3,073 and 4,433 per 1,000. These high ratios were mainly contributed to by fevers, bowel complaints, and respiratory diseases. Of the larger stations with over 1,000 men the most unhealthy were Quetta (admission-rate 1,565 per 1,000) and Jacobabad (1,493), whilst the most healthy were Belgaum (410) and Poona (706). In regard to mortality in individual stations, the highest rates on the whole prevailed also in the Southern Afghanistan stations, notably at Dhuki, where the ratio was 42·84. Respiratory diseases were the chief causes of death. The 12th Bombay Native Infantry at Pishin and its outposts suffered a heavier mortality than any other regiment, namely, 66·19 per 1,000, representing 55 deaths, due mostly to respiratory disease, bowel complaints, and fevers. The 3rd Native Infantry also at Dhuki suffered much, having lost 39 men. The 26th Native Infantry at Quetta lost 32 men. The 2nd Sind Horse, a local corps at Jacobabad, lost 25·64 per 1,000 of its strength.

Having considered individually the health statistics of the several portions of the Native Army of India in the foregoing paragraphs, it will now be convenient to contrast the main features of each, and, for convenience, the chief results are brought together in the following table:—

Presidency.	Total Deaths per 1,000 including Absentees.	Average Strength present with Regiments.	Ratio per 1,000.			
			Admissions into Hospital.	Daily Sick.	Deaths from Cholera.	Deaths from all Causes.
Bengal Native Army	12·56	40,850	1,193	35	0·71	10·97
Madras " "	11·82	28,050	836	31	1·46	10·02
Bombay " "	14·35	23,373	1,153	38	0·39	12·96
Central India Regiments	7·23	5,032	644	20	0·20	5·90
Punjab Frontier Field Force	14·06	10,458	1,262	36	—	10·71
Hyderabad Contingent	5·30	7,014	574	19	0·29	4·56
India	12·22	114,827	1,042	33	0·71	10·50

As usual, the Central India regiments and the Hyderabad Contingent show the most favourable results both as regards sickness and mortality from all causes; for the admission, daily sick, and death-ratios of these forces are the lowest of the series given in the table. The highest admission-rates prevailed in the Punjab Frontier Force and the regular Native Army of the Bengal Presidency. The highest average daily sick-ratio was recorded in the Bombay Army and in the Punjab Frontier Force. The highest death-rates were registered in the Bombay and Bengal Armies. In the Madras Army and Punjab Frontier Force the total death-ratios were nearly alike.

Jails.

Sickness and mortality in 1884.

The average number of prisoners confined in jails throughout India was considerably less than of late years. Sickness among them estimated by the admission and daily sick rates was somewhat greater than it had been during the previous year, but less than in the three years preceding 1883. Notwithstanding this slight increase of sickness the death-rate from all causes fell from 31·37 per 1,000 during the previous year to 29·11. This is the lowest death-rate on record, being less than the average death-rate during 1872–76 by 7·13 per 1,000, and less than that during 1877–81 by 33·9. The latter quinquennial period it should be borne in mind included the famine period. This satisfactory diminution in the total death-rate is mainly due to the lessened mortality from bowel complaints, which was 9·73 per 1,000 against 13·48 in the five-year period 1872–76 and 24·97 during the succeeding five years. It is noteworthy that the admission-rate from these diseases was somewhat greater during the year under report as compared with that of the previous year, namely, 175·2 per 1,000 against 164·5 in 1883. The mortality due to cholera, 1·43 per 1,000, was also below the average. The death-rate from small-pox though small was more than twice what it had been during the previous year, namely, 0·29 per 1,000 against 0·11.

Statement showing the Strength, Sickness, and Mortality among the Prisoners of India during the years 1872–76, 1877–81, *and the years* 1880 *to* 1884.

Year.	Average Strength.	Ratio per 1,000.				
		Admissions into Hospital.	Daily Sick.	Deaths from		
				Cholera.	Dysentery and Diarrhœa.	All Causes.
1872–76	99,758	1,016	2	2·86	13·48	36·24
1877–81	112,670	1,189	44·9	4·48	24·97	63·01
1880	106,763	1,213	46	0·74	19·43	48·31
1881	100,844	1,214	45	3·03	16·92	44·03
1882	94,063	1,214	42	2·75	15·21	39·96
1883	88,174	996	36	2·28	10·64	31·37
1884	85,496	1,025	37	1·43	9·73	29·11

It has already been noted that the average number of prisoners confined throughout India was less than it had been during the previous year. The decline in the numbers confined has been continuous since 1880, and during 1884 the average number of prisoners was less than the approximate average number during the 10 years 1872–81 by 20,718. The proportion of prisoners to the general population was 4·3 per 10,000 against 4·5 in 1883 and 4·6 in 1882. For the several Presidencies, the ratios are given in the following table:—

Ratio of Prisoners per 10,000 *of Population in each of the three Presidencies for* 1884, 1883, 1882, 1881, 1878, *and* 1872–76 *compared.*

Presidency.	Period.	General Population according to Census of 1881.	Prisoners.		
			Average Number.	Proportion to 10,000 of Population.	Deaths per 1,000 of average Strength.
Bengal	1872–76	47,215,384	68,328	4·6	39·39
	1878		78,116	5·3	65·85
	1881		63,478	4·3	44·42
	1882		59,489	4·0	42·56
	1883		54,982	3·7	34·28
	1884		51,877	3·5	32·71
Madras	1872–76	31,170,631	9,607	3·1	32·37
	1878		21,315	6·8	125·92
	1881		10,332	3·3	41·91
	1882		8,752	2·8	42·62
	1883		7,666	2·5	29·87
	1884		6,959	2·2	20·55
Bombay	1872–76	16,454,414	8,011	4·9	26·61
	1878		13,139	8·0	118·27
	1881		9,910	6·0	41·88
	1882		8,845	5·4	33·35
	1883		7,806	4·7	34·33
	1884		7,305	4·4	34·91

Sickness was more prevalent in the jails of the Bengal Presidency than in those of the other two Presidencies, as shown in the following table:—

Presidency.	Average Strength.	Ratio per 1,000.				
		Admissions into Hospital.	Daily Sick.	Deaths from		
				Cholera.	Dysentery and Diarrhœa.	All Causes.
Bengal	51,877	1,028	34	1·52	12·66	32·71
Madras	6,959	765	29	1·01	6·18	20·55
Bombay	7,305	702	26	0·55	7·94	34·91

The total mortality in the Bengal Presidency (32·71) was, however, not so great as it was in Bombay (34·91). The total mortality amongst the Madras prisoners (20·55) was the least, and is very satisfactory when taken in connexion with the greater prevalence of sickness among them as compared with the Bombay prisoners whose mortality was greatest. Cholera caused a smaller proportion of deaths in all three Presidencies than in the previous year; but the disease was remarkably quiescent in the jails of the Bombay Presidency. Bowel complaints were most fatal in the Bengal Presidency and least so in the Madras Presidency, where they caused only about half the mortality of the preceding year.

It has already been remarked that sickness in the jails of the Bengal Presidency was somewhat more prevalent during the year under report than it had been during the previous year, which, however, was one of exceptional results as compared with recent years. Still the admission and average sick ratios were below the averages of the five-year period 1877–81, and below those of individual years from 1878 to 1882 inclusive. The continued decline in the mortality from bowel complaints is the most satisfactory feature of the medical history of these jails. The death-rate from these diseases during the year 1884, namely, 12·66, is amongst the lowest on record. The mortality from cholera was unusually small. The total mortality from all causes (32·71) is a remarkable improvement upon that of most years: it is indeed the third lowest on record.

Year.	Average Strength.	Ratio per 1,000.				
		Admissions.	Daily Sick.	Deaths from		
				Cholera.	Bysentery and Diarrhœa.	All Causes.
1877–81	62,249	1,345	46	3·99	22·33	65·40
1877	63,300	967	30	3·07	10·59	31·88
1878	58,416	1,182	41	6·34	23·27	65·36
1879	73,901	1,335	46	6·38	30·65	77·99
1880	66,751	1,103	40	1·00	21·51	51·12
1881	63,478	1,352	41	3·10	17·21	44·42
1882	59,489	1,178	40	3·11	17·31	42·56
1883	54,862	949	32	2·35	12·93	34·28
1884	51,877	1,028	34	1·52	12·66	32·71

Fevers were more prevalent than they were during the preceding year; but the admission-rate was below the decennial average of 1873–82. Of the chief diseases enumerated in the following table causing admission into hospital four only were more than ordinarily prevalent, as compared with decennial averages. These are dysentery, diarrhœa, anæmia with debility, and venereal diseases. The type of the bowel diseases prevalent must, however, have been mild since mortality from them was considerably less than usual.

Number.	Diseases.	Decennial Average, 1873–82.	Admitted per 1,000 of Average Strength.										
			1884.	1883.	1882.	1881.	1880.	1879.	1878.	1877.	1876.	1875.	1874.	1873.
1	Fevers	488	452	389	541	528	458	660	556	371	457	398	445	450
2	Abscess and ulcer	116	94	102	123	127	133	174	113	122	115	99	107	110

The following table gives the death ratios from the diseases which have been the chief causes of mortality since 1873:—

Number.	Diseases.	Decennial Average, 1873–82.	Died per 1,000 of Average Strength.										
			1884.	1883.	1882.	1881.	1880.	1879.	1878.	1877.	1876.	1875.	1874.	1873.
1	Dysentery and diarrhœa	18·90	12·66	12·93	17·31	17·91	21·51	30·65	28·27	10·59	14·75	12·38	16·38	16·68
2	Respiratory diseases	7·18	6·03	6·00	7·26	7·52	9·38	9·53	8·32	5·41	5·45	5·01	6·02	7·00
3	Fevers	5·29	2·16	2·38	3·53	4·65	4·45	13·82	7·14	1·97	2·36	4·20	3·72	5·47
4	Cholera	3·46	1·52	2·35	3·11	3·10	1·00	6·33	5·34	3·07	4·24	2·35	2·48	2·97

10	Spleen diseases	0·35	0·27	0·34	0·19	0·22	0·57	0·31	0·23	0·20	0·29	0·77	0·37	0·23
	Total of the Ten	42·91	28·69	30·17	38·22	40·13	45·66	71·53	60·63	28·55	34·36	30·03	35·70	38·76
	Total from all Causes	47·36	32·71	34·28	42·56	44·42	51·12	77·90	65·85	31·88	37·51	33·65	39·90	43·08

It is very satisfactory to observe in this table that the diminished total death-rate was due to a diminished death-rate from every one of the chief causes of mortality with the single insignificant exception of mortality from dropsy which increased from 0·80 per 1,000, the decennial average, to 0·85 in the year under report. The most marked reduction of mortality occurred in the cases of bowel complaints, fevers, and cholera. The fever mortality is the second lowest on record since 1865, the lowest having occurred during 1877, when it was 1·97 per 1,000. Although the death-rate from respiratory diseases was below the average of the decennial period, it is still far from satisfactory when compared with the results of individual years since 1859, as the result of 1884 is worse than the results of 19 previous years. With greater attention to suitable clothing, mortality from this cause should certainly be lowered.

Sickness was most prevalent in Lower Bengal and Assam, where the admission-rate was 1,586 and the daily sick-rate 55 per 1,000, and least so in the Gangetic Provinces and Oudh, where these ratios were 629 and 24 respectively. These last ratios were very nearly approached by those of the Agra and Central India Jails, where the admission-rate was 640 and the daily sick-rate 24. The Rohilkund with Meerut and Punjab groups were much the same as regards the prevalence of sickness, for, whilst in the latter group the daily sick ratio was smaller than it was in the Rohilkund and Meerut group, the admission-rate was greater. The Central Provinces group would come fourth in point of high admission and daily sick ratios. With regard to mortality a reference to the last column of the following table shows a most satisfactory diminution in all groups in the total death-rate of the year as compared with the average mortality during 1877–81. The diminution in the Punjab is especially striking—60·09 per 1,000 less than the five years' average. Cholera was on the whole less prevalent than usual. It caused the largest proportion of deaths in the first group. The disease was unusually fatal in the fifth group. During the year 1884, as in the preceding two years, no death from this disease was registered in the sixth group. The disease was remarkably in abeyance in the Central Provinces, the death-rate having been only 0·44 against a ratio above 4 per 1,000 during the two preceding years, and an average mortality of 11·39 during the five years 1877–81. Deaths from bowel complaints were as usual most numerous in the Lower Bengal group, but it is disappointing to find the mortality for the year under review greater than that of the previous one. In every group, however, the mortality was below the quinquennial average.

Statement showing Sickness and Mortality amongst the Prisoners of the Bengal Presidency (arranged in Groups in accordance with their Geographical Positions) from 1877–81, 1882, 1883, *and* 1884.

Groups.		Average Strength.	Ratio per 1,000.					
			Admissions into Hospital.	Daily Sick.	Deaths from			Difference between Average Mortality and Year's Mortality.
					Cholera.	Dysentery and Diarrhœa.	All Causes.

	1882	13,115	1,546	45	—	15·25	41·63	
	1883	12,128	951	27	—	6·18	29·11	−60·09
	1884	11,268	1,131	27	—	7·10	28·04	

The health of the prisoners in Lower Bengal was on the whole favourable. The admission-rate fell from 1,498 during the previous year to 1,420, which ratio compares favourably also with the average of the preceding five-year period, namely 1,457. The average number of daily sick remained the same as it had been during 1883, namely 50, a higher number than the average of the preceding five years. Cholera caused 4·06 of the total mortality; this is a smaller proportion than usual. The marked reduction in the mortality from bowel complaints, which occurred during 1883, was maintained, and even improved upon, during 1884, the death-rate having been 22·83 against 23·44 in 1883, and an average ratio of 32·94 during the period 1877–81. The admission and death-rates from fevers were 473 and 224 per 1,000 respectively. The death-rate from fevers during 1884 was the lowest for nine years. Admissions from bowel complaints (497 per 1,000) were more numerous than they were in most of the preceding years, yet the mortality due to them continued to fall since 1878, and in 1884 was 22·83 per 1,000.

The highest admission-rates prevailed in the Khoolna (4,473 per 1,000) and Darjeeling (3,283) Jails. The average number of prisoners, however, at each of these jails, 74 and 99 respectively, was small, and the ratios per 1,000 do not convey any real measure of unhealthiness. Confining attention to jails with an average number of prisoners exceeding 500, the highest admission-rates were recorded in the following jails:—Alipore 2,009, Dacca 1,487, Presidency (Natives) 1,386, Midnapore 1,292, and Rajshahye 1,028. The ratios for the Alipore, Presidency, and Midnapore Jails were below those of the preceding year. In the remaining two jails coming under this category, Bhagalpur Central Jail and Buxar, the rates were comparatively low, namely, 650 and 746 per 1,000 respectively. Fevers gave rise to the largest proportion of admissions in the Khoolna, Pooree, Soory, and Chybassa Jails, in all of which the admission-rate exceeded 1,000 per 1,000. Remittent and continued fevers were remarkably prevalent in the Dacca Jail. Dysentery and diarrhœa were most prevalent in the Khoolna, Bogra, Mymensingh, Chumparun, Furreedpore, Rungpore, and Pooree Jails—all above 1,000. The highest mortality was recorded in the Rungpore Jail (256·52). This is the only jail with a mortality exceeding 200 per 1,000. Six other jails record mortalities above 100 per 1,000. Among the largest jails above enumerated the highest mortality occurred in the Rajshahye Jail (109·55—but 15·45 of this was due to cholera) and the next highest in the Dacca Jail (62·20—2·44 due to cholera). The mortality in the Buxar Jail was only 2·57, and this includes 1·06 from cholera). The largest number of cases of cholera occurred in the Rajshahye, Monghyr, and Gya Jails; in each of these 17 cases were admitted. The largest actual number of deaths from all causes occurred in Alipore 97, Rungpore 59, Rajshahye 78, Mymensingh 53, Dacca 51. In Alipore, 40 of the deaths were due to bowel complaints and 20 to respiratory diseases; in Rungpore, 30 deaths were due to bowel complaints; in Rajshahye, 11 were due to cholera and 34 to bowel complaints; in Mymensingh, 33 were due to bowel complaints; and in Dacca, 21 were due to bowel complaints and 14 to respiratory diseases. In two jails, namely, Noakhally and Arrah, there were no deaths.

The health of the prisoners of the North-Western Provinces was not so good as during the previous year. The admission daily sick and total death rates (681, 26, and 20·86 per 1,000 of average strength respectively) were all in excess of those for 1883; they, however, compare favourably with the averages for 1877–81. The increased mortality as compared with that of the previous year (19·76) was entirely due to bowel complaints.

Sickness prevailed most largely in the following jails:—Etah (admissions 3,627 per 1,000), Shahjahanpur (1,831), Muzaffarnagar (1,744), Moradabad (1,752), Muttra (1,714), Banda (1,703), Saharanpur (1,582), and Orai (1,576). In the largest jails, those containing over 1,000 prisoners, the general health was good, the highest admission-rate recorded among them having been 638 per 1,000 at Bareilly Central Jail, and the lowest, only 120, at Lucknow Central Jail. Thirteen of the 52 jails in these provinces recorded admission-rates over 1,000 per 1,000 and 19 between 500 and 1,000. Only two jails recorded total mortalities over 100 per 1,000, namely, Banda (156·78) and Almora (102·80). In the large jails with over 1,000 prisoners the total mortality from all causes was very low, ranging from 16·95 in Allahabad Central Jail to 10·29 in Lucknow Central Jail. The largest actual number of deaths occurred in—Gorakhpur 39, Banda 37, and Meerut Central Jail 28. In Gorakhpur, 30 of the deaths were due to bowel complaints; in Banda, 17 to the same cause, and in Meerut, 11 to cholera and 7 to respiratory diseases. In three jails there was no mortality, viz., Gonda, Unao, and Orai.

Sickness was somewhat more prevalent among the prisoners of the Punjab jails than during the preceding year, as is shown by the increased admission-rate, from 951 per 1,000 in 1883 to 1,131; but as the daily average sick ratio (27) did not rise the type of sickness was evidently milder. This is also indicated by the somewhat diminished total mortality ratio which fell from 29·11 during the previous year to 28·04 in 1884. Bowel complaints gave rise to increased mortality as compared with the previous year, but the ratio of the year under report (7·10) is very considerably below the average mortality during 1877–81, namely, 31·64. No deaths were caused by cholera, and this is the third consecutive year in which these jails have enjoyed such an immunity. Respiratory diseases gave rise, as usual, to the largest proportion of deaths, 8·43 per 1,000 against 9·73 in 1883. This reduction is satisfactory, but the ratio still continues to be much higher than it was in former years. During 1859–67 the average mortality from these diseases was only 2·81.

Of the 36 jails in this province three showed admission-rates above 2,000 per 1,000, and 17 ratios between 1,000 and 2,000. Thus only 16 jails remained with admission-rates below 1,000. The highest admission ratios were recorded in the following jails,—Abbottabad (2,224), Dera Ismail Khan (2,005), and the Lahore Female Jail (2,125). The ratio of the last-mentioned jail alone is in excess over those of the previous year. The Abbottabad Jail contained only 76 prisoners on an average: its high admission-rate was principally due to admissions for intermittent fevers, scurvy, and bowel complaints. In the Dera Ismail Khan Jail by far the largest proportion of admissions was due to intermittent fevers, no less than 1,317 per 1,000 of the total having been due to this cause. And the same may be said of the Lahore Female Jail, where 1,776 per 1,000 of the admissions were due to fevers. Respiratory diseases were most common in the Kohat, Muzaffagarh, Montgomery, and Gurgaon Jails, in all of which the admission-rates exceeded 100 per 1,000. The highest death-rates were recorded in the Delhi (74·42), Lahore Central Jail (58·30), and Lahore District Jail (61·10). In the Delhi Jail there were 32 deaths in all, of which 11 were due to dysentery and diarrhœa and 12 to respiratory diseases. In the Lahore Central Jail, the largest in the province, the chief causes of mortality were bowel complaints, respiratory diseases, fevers, and anæmia and debility. In the district jail, the two first gave rise to the largest number of deaths: no mortality was occasioned by fevers. In four jails no mortality was recorded, and in 17 the mortality was below 20 per 1,000.

The daily average number of sick (32 per 1,000) among the prisoners of the Central Provinces was lower than usual; but the admission-rate (932) did not fall correspondingly. The chief causes of sickness were fevers, bowel complaints, and abscess and ulcers; and the chief causes of death bowel complaints, anæmia, and debility. The mortality from all causes, 42·02, shows a very satisfactory reduction upon that of the preceding two years, namely, 70·97 in 1883 and 71·05 in 1882. It is considerably below the average for these provinces, though by no means the lowest on record. The reduction has been mainly due to the diminished mortality from bowel complaints, which is extremely satisfactory. It was noted in the report for 1883 that the mortality from these diseases during that year was the highest on record since 1859, and that it exceeded the average of the preceding 20 years by 24·18 per 1,000; but the ratio of 1884 is below this average. Cholera was practically absent, only one death having occurred from it.

There are six jails in these provinces with an average population exceeding 100; three of which, Raipur, Nagpur, and Jubbulpur, have over 600 prisoners. In the Nagpur Jail, the admission-rate was 1,343, whilst in Raipur it was only 732. Fevers and respiratory diseases were much less prevalent in Raipur than in Nagpur, which mainly accounts for this difference in the admission-rates. The highest mortality was recorded in the Sambalpur Jail 70·97; of the 11 deaths which gave rise to this ratio 9 were due to dysentery and diarrhœa. In the Raipur Jail there were 35 deaths in all, 17 of these were due to dysentery and diarrhœa and 8 to anæmia and debility. In the Nagpur Jail there were 34 deaths, 15 and 5 due, respectively, to the same causes.

The vital statistics of the prisoners located in the jails of Berar were very favourable. The daily average number of sick (11 per 1,000) was remarkably low. For the third consecutive year no death from cholera took place. Compared with other jails deaths from bowel complaints were very few, whilst the total mortality (8·72) was considerably less than a third of the average for 1877–81.

There are only two jails of considerable size in this province, those at Amraoti and Akola. The admission-rates in these jails were 457 and 426 respectively; there were no deaths in any of them with the exception of the Akola Jail, in which there were nine. Bowel complaints, respiratory diseases, and phthisis caused two deaths each.

The health statistics of the prisoners in Burma show an improvement upon those of the preceding two years; but they do not compare favourably with the average results of the five-year period 1877–81. The total mortality among them (30·28) was higher than it had been during the two previous years (28·94 in 1883 and 27·81 in 1882), notwithstanding a diminished death-rate from cholera. The increased mortality over that of the previous year was mainly due to a larger number of deaths from anæmia and debility, small-pox, bowel complaints, hepatitis, dropsy, apoplexy, and respiratory diseases. The diminished admission-rate (936 against 1,159 in 1883) was mainly due to the lessened prevalence of cholera, continued fevers, bowel complaints, eye diseases, and injuries.

The highest admission-rate, 1,312, was recorded in the Rangoon Jail, the largest in the Administration. Admission-rates were also high in the Akyab, Shewgyin, and Myanaung Jails, all over 1,000 per 1,000. The last two jails are, however, very small. The largest mortality occurred in the Akyab Jail, viz., 129·19 per 1,000, but this was largely contributed to by cholera. Of the 54 deaths which took place in that jail 22 were due to this disease. In the Rangoon Jail the mortality was not great, namely, 23·52.

Sickness continued to be very prevalent among the prisoners of Assam. The admission and daily sick rates were practically the same as during the preceding year, and they were considerably above the average. Fevers and bowel complaints were the main causes of admission, together contributing 1,313 per 1,000 to the total admission-rate of 2,109. The total mortality ratio, 61·19, also rose considerably above those of the last four years. The total death-rate rose from 43·12 in 1883 to 61·19, the increase being mainly occasioned by bowel complaints, which rose from 16·58 to 24·16, by respiratory diseases, which rose from 2·49 in 1883 to 11·27 in 1884, and by fevers, which rose from 2·49 to 5·64. Cholera was very prevalent, having caused 5·64 per 1,000 of the total mortality.

There are five jails in this province, only one of which is of considerable size, viz., that at Sylhet, with an average strength of 517. The admission-rate in this jail was very high (2,288). Of the 36 admissions for cholera which were made throughout the jails of the province, 25 took place in the Sylhet Jail, all during August. Of these, however, only two died. There were 12 deaths in this jail from bowel complaints, and six from respiratory diseases.

There was a considerable amelioration in the health of the prisoners in Madras; the admission and daily sick ratios (765 and 29 per 1,000) were less than usual, and the total mortality fell very considerably. It was 20·55 against 29·87 in 1883 and an average of 63·98 during the 20 preceding years; the death-rate of the year under report is, in fact, the second lowest on record, the lowest having been 17·9 in 1871. The main cause of the reduced total mortality, as compared with many former years, has been the smaller death-rate from bowel complaints, which was only 6·18 against an average of 25·72 for the 20 years previous to 1882. But in addition to this, most of the chief causes of mortality gave rise to smaller ratios, and cholera was less prevalent than usual.

Of the 30 jails in this Presidency nine recorded admission-rates between 2,000 and 1,000 per 1,000 and eight under 500. Of the larger jails, the Rajahmundry Central Jail and the Cannanore Jail yielded the highest admission-rates, 1,329 and 1,135 respectively. In the remaining large jails these ratios varied from 395 in the Trichinopoly Central Jail to 718 in the Salem Jail. All these ratios are below those of the preceding year. Twenty-one cases of cholera in all were treated, and of these seven died: 17 of the cases with five deaths occurred in the Cuddalore Jail. Of the total number of deaths which occurred throughout the jails of the Presidency, namely, 143, 43 were due to bowel complaints, and 17 of the 30 jails recorded deaths from this cause.

The vital statistics of the prisoners of Bombay were, on the whole, favourable. The admission and daily sick ratios (702 and 26 per 1,000) were lower than those of the preceding year, but the total mortality (34·91) was fractionally greater. Excluding mortality from cholera from both years, however, the comparison is less favourable, for, whilst in 1883 cholera caused 2·05 of the mortality, during 1884 only 0·55 per 1,000 were attributable to the same cause. Still, compared with the average death-rate during the 18 years previous to 1883, namely, 47·15, that of the year under report is favourable. Bowel complaints caused a slightly higher mortality than they did during the two previous years.

Seven of the 32 jails of this Presidency recorded high admission-rates, ranging between 1,000 and 2,000 per 1,000, and eight recorded rates below 500. Most of the jails which recorded high rates were small. Among the larger jails these ratios varied from 279 in Ahmedabad to 998 in Nara. Fevers, bowel complaints, and respiratory diseases were the most frequent causes of admission. Fevers were most prevalent in the Mhasvad gang, Ahmednagar, Sawantwari, and Kaladgi Jails, whilst bowel complaints were most frequent in the Rajkot, Poona, Sholapur, and Ahmednagar Jails. The largest number of deaths, both actual and proportional, occurred in the Nara Jail. Of the 67 deaths which took place there, 29 were due to respiratory diseases, 12 to fevers, and 12 to bowel complaints. This large mortality was mainly due to the accidental burning of the jail, which left the prisoners exposed to the weather for some days. The next largest number of deaths (44) took place in the Shikarpur Jail, most of which were due to the same diseases. In five jails no deaths took place.

A very satisfactory condition of health was observed among the convicts at the Andamans. With the single exception of the admission-rate (1,465 per 1,000), which is but nominally greater than that of 1883, the results of the year under review were most favourable. The daily sick-rate was 65 per 1,000 against 67 in 1883, and the death-rate 15·75 against 19·63. The reduction in the mortality from bowel complaints, from 2·87 to 1·80, as well as in the total mortality, is remarkable and most satisfactory. As explained in the report for 1883, these results have been brought about mainly by the care which is now bestowed upon the acclimatisation of the convicts before they are put upon unhealthy works and to their greater shelter during inclement weather.

General Population.

General remarks.

In the North-Western Provinces with Oudh, Punjab, Central Provinces, and Berar, birth-rates exceeded 40 per 1,000 of the population. In Bombay the total birth-rate was 32·50, whilst in the remaining provinces it varied from 14·87 in Coorg to 29·3 in Madras. In only three provinces the death-ratio exceeded the birth-rate, namely, in Bengal (by 6·35 per 1,000), Assam (by 2·76), and Coorg (by 0·21). The excess of births over deaths was most marked in Berar, where the birth-rate exceeded the death-rate by 16·7 per 1,000, whilst the smallest excess was shown by Burma, namely, 4 per 1,000. Excluding Mysore and Coorg, in which registration is but partially and imperfectly conducted, the most uniform results in birth registration were obtained in Berar and the Central Provinces. The difference between the maximum and minimum ratios of districts in Berar amounted only to 8 per 1,000, and in Central Provinces to 13·84. In Bengal and Punjab the difference exceeded 40 per 1,000; in the North-Western Provinces it amounted to 35·66, and in the remaining provinces varied from 29·0 in Assam to 17·03 in Burma. The highest death-rate was recorded in the North-Western Provinces and Oudh, namely, 35·26 per 1,000, and the lowest in Burma, 18·95 (excluding Mysore and Coorg). The most uniform results in the registration of deaths were also obtained in Berar and the Central Provinces, the extreme variation in districts of the former province being 7·1 per 1,000, and in the latter 10·85. The greatest variation was recorded in Assam, amounting to 55·52 per 1,000. Cholera gave rise to the largest proportion of deaths to population in Assam (4·92); in Bengal and Madras it gave rise to a little over 2 per 1,000 of population. Small-pox was most prevalent in North-Western Provinces and Oudh, where it occasioned 4·59 per 1,000 of the total death-rate. Mortality from fever was greatest in the Punjab (24·71 per 1,000) and least in Madras.

During 1884 another town was added to the number of municipalities in Bengal Proper in which registration of births is carried out. The total births recorded amounted to 39,640, or at the rate of 23·51 per 1,000 against 22·08 in 1883. These ratios are manifestly much under-estimated, and when the ratios of individual towns are examined, it is evident that registration is very imperfectly performed. Of 47 towns, only two recorded a birth-rate above 40 per 1,000, seven between 30 and 40, 19 between 20 and 30, 15 between 10 and 20, and four below 10. The deaths in the province during 1884 numbered 1,378,610, or at the rate of 20·83 per 1,000 against 18·82 in 1883 and 20·41 in 1882. The ratio of 1884, like the birth-rate, is also in all probability much under the truth. The district ratios disclose still more unsatisfactory results, for of 45 districts in no less than 25 the ratios were below the provincial average. In rural circles the mortality was 20·58 per 1,000, or 0·25 less than the average for the province, but in towns the death-rate averaged 27·43 per 1,000.

In the North-Western Provinces and Oudh, the general registration of births was introduced in 1879, and in that year the recorded birth-rate equalled 28·69 per 1,000. Since then there has been considerable improvement: By a gradual increase the ratio in the year under review stood at 43·77. This improvement has been very general over the Provinces. Only three districts, Dehra Dun, Kumaon, and Allahabad, still show imperfections. In the 106 towns where registration is carried out under municipal agency, the birth-rate was 40·08. The male births of the Province show a preponderance of 10·97 per cent. over the female births. Owing to the comparative unhealthiness of the year, aggravated to a great extent by an excessive rainfall during the autumn months, the total number of deaths amounted to no less than 1,555,342, or 339,045 more than in the preceding year. This high mortality has not been equalled by that of any year since 1870, excepting the famine year 1879; and notwithstanding the high rates of births in the districts, in nine instances the death-rates exceeded the birth-rates by ratios varying from 1·10 to 15·27 per 1,000. The average death-rate of the Province was 35·26 against 27·57 in 1883. The mortality among infants less than a year old was exceedingly high, the proportion among boys having equalled 451·50 per 1,000, and among girls 407·73; and considerably more than one-half of the total deaths was among children under five years of age. The mortality in rural circles was 34·78 per 1,000, and in towns 42·47.

With a view to secure accuracy in the Punjab, the compilation of primary returns of births and deaths has since the commencement of 1884 been carried out by the Civil Surgeons of districts under the orders of the Local Government; and the results of the year bear indication of marked improvement. The births registered in the Province amounted to 809,912, or at the rate of 42·98 per 1,000, against 734,912, or 39 per 1,000 in 1883. This increase was general throughout the Province: in fact, with the exception of Simla, Peshawar, Dera Ghazi Khan, and Kohat, the district ratios elsewhere were all above 34 per 1,000, while the highest ratio in any one district was 58·59. That the average birth-rate of the Province was not much under the truth is further confirmed by the results obtained in 49 principal municipalities where the increase to population by births averaged 42 per 1,000. The low ratios of Kohat, Dera Ghazi Khan, and Peshawar are probably due to imperfect registration at those places, but that of the Simla district is no doubt affected to a great extent by the migratory nature of the population of the sanitarium. The male births everywhere preponderated over the female births, the average excess for the Province being at the rate of 14·7 per cent. Compared with the preceding four years, the year under review has been somewhat unhealthy. The total deaths of the Province numbered 660,298, or 184,557 more than in the previous year. These numbers represent ratios of 35 per 1,000 in 1884 and 25 in 1883. The increased death-rate of 1884 may in part be attributed to improved registration, but principally to the great prevalence of fevers during the autumn months. The deaths among men averaged 34 per 1,000 against 36 among women. Out of a total of 32 districts the mortality in 7 only was below 25 per 1,000, while in the others it ranged between 65 in Ludhiana and 25 in Dera Ismail Khan. The districts which yielded high rates of mortality (varying from 40 to 65) were Ludhiana, Karnal, Umballa, Delhi, Hoshiarpore, Ferozepore, and Gurdaspur; and in all of these except the last two districts the death-rates were higher than the birth-ratios. More than one-half the total deaths of the Province were among children under five years of age. The urban mortality of the Province generally as well as the death-rate of the 49 selected municipalities was 41 per 1,000, and the rural death-rate was the same as the average for the whole Province, viz., 35.

During 1884 the number of births registered in the Central Provinces was 368,036, or at the rate of 41·75 per 1,000 of population as compared with 40·59 in the preceding year. Of these 190,702 were boys and 177,384 were girls, the excess of the former over the latter being at the rate of 7·5 per cent. The births were everywhere more than the deaths, and the net increase to population, therefore, during the year was at the rate of 14·45 per 1,000. The deaths in all numbered 240,714 against 241,467 in 1881, and still higher numbers in the two intermediate years. Of these nearly one-third was among infants less than a year old and more than one-half among children under five years of age. As in the case of births, the death-rate in towns was also less than in the rural circles. The total death-rate of the Province was 27·30 per 1,000 against 34·56 in 1883. This reduction may have been due to the healthy character of the year. In all municipalities a bye-law exists to facilitate the registration of births and deaths, and the Chief Commissioner has drawn attention to the necessity of enforcing its operation strictly.

A revised system of registering vital statistics has been in force in Berar since the commencement of 1883, and has been found to work well. But sufficient accuracy has not yet been attained. During the year under review 108,725 births were registered in the Province, or at the rate of 41·3 per 1,000 of population. This number is the highest on record since 1868, with the single exception of 1882. For every 100 births of girls 107 boys were born during the year. In rural circles the births were at the rate of 41·6 per 1,000, and in towns at 38·7. Compared with 1883, the birth-rate was less in 10 of the 34 towns in the Province. In all districts the births were more numerous than deaths, the excess varying from 14·2 per 1,000 in Akola to 19·3 in Buldana, or on an average there was a net increase of 16·7 per 1,000 to the population of the Province. There were altogether 64,808 deaths during the year equivalent to 24·6 per 1,000. This ratio evidently understates the true mortality of the Province. The ratios of districts varied from 20·1 to 27·2. The male deaths exceeded the female deaths by 9·7 per cent. More than one-half the total mortality was among children under five years of age. Rural circles returned a death-rate of 24·6 per 1,000 against 27·4 in towns. These figures, however, do not admit of comparison with the statistics of the previous year, when the mortality assumed unusual proportions owing to epidemic cholera and excessive prevalence of fevers, bowel complaints, and small-pox.

In 1884 the accession to the population of British Burma by births amounted to 82,783 and the loss by deaths to 69,234. These figures yield a birth-ratio of 22·66, and a death-rate of 18·95 per 1,000 against 22·92 and 14·67 respectively in 1883. These results indicate some improvement as compared with the past year. The death-rate is the highest on record during the last 10 years. The average death-rate for the Province as a whole has been vitiated by the inclusion of rural statistics, for whilst the urban mortality, 36·65, must be near the truth, the rural mortality, 16·61, is evidently under-stated. A new system of registration, however, was introduced in some districts late in 1884 and in others from the commencement of the current year, and it is expected that the figures of 1885 will be much more accurate than those of past years. As usual, registration generally seems to have been more accurately carried out in towns than in the interior of districts. In the towns as a whole the birth-rate averaged 23·28 per 1,000 of population. This ratio cannot be accepted as strictly correct, being apparently too low. In rural circles births were recorded at the rate of 22·58 per 1,000 and deaths at 16·61.

Births were recorded in Assam of 62,941 boys and 57,542 girls, or a total of 120,483 children, equivalent to 26·61 per 1,000. This ratio, however, was made up of extremes varying from 19·38 in the Lakhimpore district to 41·65 in Goalpara and 48·38 in the town of Tura. Both the district and provincial ratios testify to considerable improvement having been made in registration during the year under review, but as in all districts except one the recorded mortality was in excess of the births, the results must still be far from accurate. Male births exceeded female births by 9·38 per cent. on an average for the Province. The loss to population by deaths amounted to 132,992, or 12,509 in excess of the registered number of births. The average death-rate of the Province was 29·37 per 1,000. As in the case of births, Lakhimpore recorded the lowest death-rate, 21·08 per 1,000, and Goalpara the highest, 49·50. More than one-third of the total mortality took place among children under five years of age. In 22 towns registration is compulsory, but the results obtained in several of them appear to be less correct than those recorded in districts where registration is voluntary. Registration in tea-gardens shows a considerable improvement on the results of the preceding year, as in them the birth-rate was 31·66 per 1,000 and the death-rate 40·91. This death-ratio is high, but in connexion with it the fact must be borne in mind that the coolies in these gardens are all imported and subjected to climatic conditions differing often considerably from those to which they have been accustomed.

The results of registration in Madras Presidency during 1884 bear indications of greater accuracy in the recording of vital statistics than in any of the preceding years since 1869. But better as they are, there is still much room for improvement. The births numbered 827,381, or at the rate of 29·3 per 1,000 against 27·7 in 1883, which again was the highest ratio recorded in any year since the commencement of birth registration in this Presidency. Of the total births 15 per 1,000 were boys and 14·3 girls. The births in all the districts were in excess of the deaths except in Godavari, Tanjore, and Tinnevelly. The loss to population by deaths during the year amounted to 650,335, or at the rate of 23·1 per 1,000 against only 19·0 in the previous year. This increase may have been partially due to improved registration, but there is no doubt that it was mainly owing to the great prevalence of epidemic cholera, small-pox

fevers, and bowel complaints. That little progress has yet been made in the registration of deaths is apparent from the very great variation in the death-rates of districts, where they ranged between 14·5 in Ganjam and Nellore to 35·7 in Tanjore. In the city of Madras deaths were recorded at the rate of 49·4 per 1,000. In the rural circles the death-rate was 22·7, or 0·4 less than the average for the Presidency; but in towns the average mortality of the year was 27·7 per 1,000.

In the Bombay Presidency the births of the year amounted to 534,723 against 501,891 in 1883 and a mean of 368,558 for the 10 years 1874–83. The average birth-rate of the Presidency during the year under review was 32·50 per 1,000, which is higher than that of any year since 1874. It is made up, however, of extremes, varying from 16·91 in Hyderabad to 43·43 in Dharwar. The statistics of the city of Bombay and the Sind districts still show great imperfections. The excess of boys over girls born during the year was 9·09 per cent., and the average excess of births over deaths 7·68 per 1,000. The deaths recorded during the year numbered 408,409, or at the rate of 24·82 per 1,000 against 420,198 and 25·53 in 1883. The maximum mortality occurred in November and the minimum in June. In rural circles the death-rate was at 24·17 and in towns at 29·25 per 1,000. Cholera was less prevalent than in the preceding year, but the deaths from small-pox, fevers, and bowel complaints were more numerous than in 1883.

The results of the registration of births and deaths in Coorg in 1884 are far from encouraging. A birth-rate of 14·87 per 1,000 and a death-rate of 15·08 are manifestly incorrect. In all 2,652 births were recorded, Of these 1,349 were boys and 1,303 girls. The deaths numbered 2,689, the majority of which was due to fevers. Not a single death is stated to have been caused by cholera during the year.

History of Chief Diseases.

Cholera.

The total number of deaths caused by cholera throughout those parts of the Indian dominions in which registration is effected exceeded that of the previous year, the numbers being 287,609 in 1884 and 248,860 in 1883. The largest aggregate number of deaths in any one Province was recorded in Bengal, but the highest proportion of deaths to population occurred in Assam, where this ratio was 4·92 per 1,000. Of the 14 provinces enumerated in the following table only four recorded fewer deaths than during 1883, namely, the Central Provinces, Berar, Central India, and Bombay:—

Annual Deaths from Cholera in India, 1874 to 1884.

Province.	Population.	Deaths from Cholera.										
		1874.	1875.	1876.	1877.	1878.	1879.	1880.	1881.	1882.	1883.	1884.

* Excluding Calcutta. † Statistics not available. ‡ Population not known.

In the Central Provinces and Berar the reduction over the numbers of the preceding year was very marked, but these provinces are especially liable to invasions by the disease in remarkable epidemics of intense severity followed by periods of considerable quiescence. The main burden of the excess in the aggregate number of deaths from this cause throughout India over that of the preceding year was borne by Bengal proper and Madras.

In Bengal Proper the largest number of deaths occurred as usual early in the year, the maximum number having been recorded in April. In Assam the maximum was reached in May, and in the North-Western Provinces not until August. In the Madras

Presidency the disease caused the largest mortality as usual during the cold months, whilst in the Bombay Presidency the period of greatest mortality coincided most closely with that of the North-Western Provinces, namely, July and August.

In Bengal the disease was widely prevalent after a year of comparative abeyance. In this Province 134,421 persons died of the disease, a number exceeding that of the previous year by 43,982, and yielding a mortality of 2·03 per 1,000 against 1·36 during 1883 and 1·59, the average of the previous five years. The disease prevailed with special severity in Orissa, where 4·95 per 1,000 of population fell victims to it against an average ratio of 2·97 during the preceding five years. In Bengal Proper also, the incidence of the disease was severe, causing a mortality of 2·71 per 1,000 against 1·51 during the previous five years. In Behar and Chota Nagpur it was less prevalent, giving rise to mortalities of 0·76 and 0·79 per 1,000 respectively. Throughout the Province 10·8 per cent. of villages were affected, varying from 24·29 per cent. in the Presidency division to 2·24 per cent. in Chota Nagpur. As regards the seasonal prevalence of the disease, the months of greatest prevalence for the province, as a whole, were April and May and November and December. The season of maximum intensity varied, however, in different parts. In Bengal Proper March to May and October to December were the months of greatest mortality, whilst in the remaining parts, Behar, Orissa, and Chota Nagpur, May to August were on the whole the worst months. Urban mortality throughout the Province was 3·81 and rural 1·96 per 1,000.

Cholera was unusually prevalent in Assam; indeed the mortality from this cause throughout the Province, 4·92 per 1,000 of population, is the highest on record. The disease prevailed severely in every district, but was most severe in Nowgong, where deaths were in the ratio of 8·95 per 1,000. In the Darrang and Sibsagar districts the mortality exceeded 6 per 1,000. For the Province as a whole deaths from cholera began to increase in March and gradually but quickly reached a maximum in May. Thereafter the numbers declined until in September they were fewer than they had been in March; but in October the disease was rekindled and gave rise to many deaths. In regard to the seasonal prevalence of the disease some differences are observable in its progress through the Brahmaputra and Surma valleys. In the Surma valley the disease showed signs of activity earlier, the number of deaths due to it beginning to rise in February, and its autumnal resuscitation was both earlier and more intense, commencing in September and attaining a severity in November, exceeding the maximum intensity of the earlier epidemic period which was attained in May. In the Brahmaputra valley deaths from this cause did not begin to rise appreciably until March, and the highest number was recorded in June, whilst the autumnal recrudescence was but little marked. In this Province the urban and rural death-rates from cholera did not differ much: in towns the death-rate was 4·49 and in rural circles 4·93. Throughout the Province 21·9 per cent. of villages were attacked.

The history of cholera among immigrant coolies to Assam during 1884 presents several features of interest, for although the disease prevailed with unusual severity in the districts of the Brahmaputra valley, these coolies escaped to a remarkable extent. Whilst mortality from cholera in the districts of the Brahmaputra valley as a whole equalled 5·8 per 1,000 of population, that amongst immigrant coolies was 1·4 per 1,000, and much of even this mortality may have been due, as will be shown below, to unfavourable influences acting upon them before they entered the province of Assam. The table in the margin exhibits the deaths from all causes since 1877, and shows that the death-rate among the coolies during 1884 was amongst the most favourable on record. The mortality ratios of 1880 and 1881 are certainly lower than the ratio of 1884, but when the large increase in the number of immigrants during 1884 and the progressive improvement in registration are taken into consideration, the result of 1884 may fairly be regarded, in the words of the Sanitary Commissioner of Assam "as the best record "of successful sanitation." During 1884, 26,270 immigrants entered Assam against 16,983 in 1883 and 10,454 and 11,250 during 1880 and 1881. Among the large number of immigrants during 1884, 68 deaths from all causes took place on the river, of which 37 were due to cholera. It is interesting, however, to observe that no less than 32 of these deaths occurred "when the coolies were sent "hurriedly away from the depôts in consequence of epidemic cholera at Dhubri," their starting point in Assam. The whole number of deaths from cholera was distributed in time as follows:—2 in January, 18 in February, 8 in March, 6 in April, 2 in May, and

Year.	Number of deaths on the river.	Ratio per mille.
1877	904	29·9
1878	794	33·8
1879	106	8·2
1880	23	2·2
1881	18	1·6
1882	106	6·5
1883	138	6·6
1884	68	2·6

1 in November. Comparing this seasonal distribution of deaths among coolies with the mortality from cholera by months among the inhabitants of the districts bordering the Brahmaputra river, it appears that the great majority of deaths among coolies occurred before the disease became epidemic in the bordering districts. The districts through which the coolies pass on their upward journey from Dhubri to Dibrugarh are in succession Goalpara, Kamrup, Darrang, Nowgong, Sibsagar, and Lakhimpur, but the last-named district has little connection with the river. In Goalpara the disease did not become epidemic until May, and prevailed with maximum intensity during June and July. In Kamrup it began to increase in April, and was most prevalent during May, June, and July. In Darrang it prevailed epidemically from April to June, and in Nowgong from June to August, with some diminution in September and renewed activity in October and November. In Sibsagar the months of greatest prevalence were March to June. Thus, during February and March, when 26 of the whole 37 deaths occurred among coolies, cholera did not prevail with epidemic intensity in most of the districts through which they passed; and 34 deaths preceded the month of maximum intensity of the disease in any district. The occurrence of one death from cholera of a cooly in November is interesting, as during this month a recrudescence of the disease occurred in the Nowgong district as has already been noted, and cholera prevailed intensely. Turning next to the history of the disease at Dhubri, the most striking fact is that cholera prevailed there most severely, considerably before the district as a whole was invaded epidemically. The Medical Officer at Dhubri reports that cholera prevailed epidemically in the cooly depôts during February, March, and April, but of the 137 men attacked, 24 arrived with the disease, 30 were admitted into hospital for it within 24 hours, and 33 within 48 hours of arrival. Thus a large number of deaths occurred within 48 hours of their arrival. Moreover, it is stated that about 15 deaths occurred among coolies on board the railway steamers before they could reach the depôts, and which are therefore not included in the 137 total cases above referred to. But although cholera was not epidemic in the Goalpara district in which Dhubri is situated during those months, it was springing into activity in the Burdwan district of Bengal through which these coolies passed, and where they probably rested, as cooly depôts are established in it. Cholera deaths in that district were registered as follows:—January, 46, February, 28, March, 323, April, 1,003, May, 421.

The late Sanitary Commissioner with the Government of India, in considering the history of outbreaks of cholera among these coolies, was of opinion that on the whole coolies suffered in common with the people through whom they passed, as the conditions favorable to the development of the disease were common to all. He pointed out that such a view did not necessarily imply liability on the part of the coolies to attack contemporaneously with the maximum prevalence of the disease among the inhabitants of the country through which they passed, and in support of his argument he adduced the well-known fact that certain villages of an epidemically affected area suffered severely sometimes at a time when the maximum intensity of the disease for the area as a whole had either passed by, or had not as yet been attained, whilst others escaped affection altogether; in other words, that the history of localised outbreaks of cholera showed that affected areas are by no means uniformly attacked either in space or time. Whilst a given community of coolies are travelling through an affected district, be it by land or water, they may be regarded as a village of the district, and as such liable to attack or immunity in common with other communities of the district, and all that can be done in the present state of our knowledge to avert the attack either of a fixed or a moving community is to improve its sanitary condition and make it as perfect as possible. With improved sanitation in all its aspects, whether accomplished in a village or on board a steamer, we have every reason to look for a lessened liability to sickness, and this is true not only of cholera, but of disease generally. During the year under report the communities of coolies passing up the Brahmaputra river may be regarded in the same light as the more fortunate villages of the districts through which they passed, which escaped attack altogether or which suffered but little. It is not to be denied, however, that the history of the disease admits of a different interpretation. It may be argued that there is much in the history of the year under report to show that the disease was contracted before they entered Assam, and that it was consequently imported by them. It is difficult to determine which of these views may be the correct one, but fortunately from a practical sanitary point of view it is immaterial which view is accepted, for experience shows clearly that the only means in our power to diminish liability to attack of communities is a scrupulous attention to general sanitation. Much has been done of late years to improve the

sanitary condition of the surroundings of the coolies, and in consequence there has been diminished prevalence of sickness and lessened mortality. Before closing this paragraph it is desirable to call attention again to the effect the introduction of a faster steamer service may exert upon the liability to attack of the coolies whilst passing through affected areas. It is evident that the more quickly bodies of men are passed through affected areas, the less liable they will be to contract the disease, whether we believe the disease is caused by a variety of unfavourable influences surrounding the locality or to a particulate entity. Moreover, with an improved system of transport not only are the consequences of prolonged subjection to unfavourable influences surrounding affected areas considerably lessened, but many of the evils generally attendant on the close aggregation of large bodies of men are removed. Whilst formerly slowly moving ships carried from 500 to 600 coolies on board, the steamers of the fast service introduced towards the end of 1883 carry only 175 souls on board. During 1877–78 nearly 70 per cent. of immigrant coolies embarked at Goalundo, and the journey from that port to their destination, Dibrugarh, occupied 16 days. During 1883 only 18·87 per cent. of coolies embarked at Goalundo, the remainder embarking at Dhubri, and the voyage for the greater number lasted about 12 days. During 1884, 90 per cent. embarked at Dhubri, and the voyage was shortened to an average of 4 days and 20 hours. The beneficial effect of this acceleration in transport cannot be over-estimated. The evidence afforded by the history of cholera among these coolies has often been adduced in support of the most various and contradictory views of the causation of the disease. It is evident, however, from the history just given that sanitary measures to improve the surroundings of coolies during their progress up the river have followed one another so rapidly that the effect of the introduction of any one of them on the causation of this still mysterious disease cannot be distinctly traced. Of the various explanations, however, which have been offered to account for the diminished prevalence of cholera among them of late years, that given by Dr. De Renzy, the late Sanitary Commissioner of Assam, that an improved water supply is the chief cause, cannot be accepted, for Dr. Eteson, the present Sanitary Commissioner, writes:—"The coolies who alone are provided with protected and filtered water alone get cholera; other passengers who always draw water over the side and at landing places where the steamer stops and pollution is most probable never get it. The crews of all the steamers use unprotected "water, and are never attacked." In conclusion, it may be stated that Dr. Eteson believes that the production of cholera among these coolies can be attributed to no single cause, but to a variety of concurrent insanitary conditions, and he attributes the immunity experienced by them during 1884 to the following causes:—

(1) To the avoidance of over-crowding; the mail steamers carrying small batches of 175 souls instead of several hundreds as formerly.
(2) To the speed of transport, not because they are carried quickly through affected areas, but because the speed ensures thorough perflation and ventilation.
(3) To the greater attention paid to the medical inspection of coolies at Dhubri, resulting in the provision of better food, clothing, medicines, water, bedding, medical comforts, &c.
(4) To the improved general sanitary arrangements on board, more especially with regard to cook-houses, latrines, general and hospital accommodation.

Though more prevalent than during the preceding year, cholera was not unusually prevalent in the North-Western Provinces, as compared with a series of past years. The disease gave rise to 30,143 deaths, or 0·68 per 1,000 against 18,160 or 0·41 during 1883. The mean ratio of mortality during the previous five years was 1·09. It should be noted that the year 1883 was remarkable for the quiescence of the disease. It appeared in an epidemic form only in the Trans-Jumna districts, Hamirpur, Banda, Jalaun, and Jhansi. The two last-mentioned districts had not suffered epidemically from the disease since 1870, the year in which the registration of cholera deaths was commenced in them. But although the disease in an epidemic form was confined to these four districts, it was nevertheless very widely prevalent to a lesser degree; for of the 49 districts in the Provinces, all but two returned some deaths from this cause. Again, 57 per cent. of registration circles reported deaths and 3 per cent. of all villages. The months of greatest prevalence were May, June, August, and September. It was again observable that the movement of the disease was in general from the south-east to the north-west. In the four most largely affected districts the death-ratios were—Hamirpur 6·13, Banda 2·32, Jalaun 4·92, and Jhansi 5·62. The mortality in towns equalled 1·73 per 1,000, whilst in rural circles it was 0·61.

In the Punjab cholera caused 614 deaths, or 0·03 per 1,000, against 190 or 0·01 in 1883. The death-rate for 1884 was still considerably below the average, for the mean

ratio of the preceding five years, including periods of remarkable quiescence of the disease, was 0·36. Moreover, the disease was very confined in its area of incidence, for of the total number of deaths no less than 526 occurred in one district, Kangra. Unfortunately the history of the disease in this district was not available, but most of the deaths were reported to have occurred in May, June, and August.

The disease in the Central Provinces was less prevalent not only as compared with the past year, but also with the nine preceding ones. It gave rise to 149 deaths only against 16,235 in 1883, or a ratio of 0·02 against 1·84 in 1883 and 1·64, the mean of the preceding five years. Of the total number of deaths recorded in 1884, 84 occurred in Nimar, 29 in Chanda, and the rest in small numbers over six other districts. The disease appears to have commenced in the western districts, the first reported case having occurred on the 6th March in the Nimar district. On the 14th of the same month it appeared in the Narsinghpur district, passing over the intervening district, Hoshangabad, in which the disease did not appear until July. During August the Provinces were entirely free of the disease, but in September the Jubbulpore and Chanda districts became affected, and this initiated a second outbreak which happily subsided during December, when only one death was reported throughout the Province. Of 27,674 villages in the Province only 40 were affected, or 0·14 per cent. The ratio of mortality in the district and in towns was identical, namely, 0·02 per 1,000.

In the Hyderabad Assigned Districts, cholera was remarkably little prevalent. It gave rise to 87 deaths in all, a ratio of 0·03 against 27,897 or 10·6 in 1883. Of the 87 deaths 51 occurred in Buldana, 30 in Akola, and 6 in Ellichpur; the remaining three districts of the Province enjoyed a complete immunity from the disease. In Buldana the disease appeared in two distinct outbreaks separated by a comparatively long interval. The first, which was a slight one, occurred in May, and died out after causing five deaths; the second began in September. In Akola all the deaths recorded took place in November. In both these districts the Civil Surgeon inspected the affected places at the time, and in each instance the origin of the disease was attributed to local causes, no connection having been established between affected localities and other known affected sources. Of 113 circles of registration in the Province 10 only were affected, and only 19 villages out of a total of 5,501. The disease was therefore remarkably confined in the area over which it prevailed. The total number of persons attacked is stated to have been 209, so that the percentage of deaths to seizures was 41·6—a comparatively low proportion.

Cholera gave rise in British Burma to a larger number of deaths than in 1883 by 3,330, the total numbers for each year being 2,185 in 1883 and 5,515 in 1884. The deaths during 1884 represent a mortality of 1·51 per 1,000, the mean average of the preceding five years being 1·08. Whilst in 1883 cholera was most prevalent during the first half of the year, during 1884 its ravages were greatest in the latter half. Again, almost all the districts which suffered least in 1883 had a larger number of deaths in 1884. But although the disease was very prevalent, it was confined in the area over which it occurred, for of 843 circles only 137 were affected, and only 1·5 per cent. of the villages of the Province were affected. The Arakan division suffered most in proportion to population, the mortality ratio per 1,000 of population being 2·11; but the largest aggregate number of deaths were recorded in the more populous Irrawaddy division. The disease caused proportionately twice as many deaths in towns as in rural circles, the ratios being 2·68 and 1·36 respectively. Of towns, Pantanaw (with a mortality ratio of 8·58 per 1,000), Henzada (7·65), Yandoon (7·18), and Prome (7·08) suffered most.

Cholera in the Madras Presidency caused twice as many deaths as it did during the previous year, namely, 75,476 deaths equal to 2·7 per 1,000 of population, against 0·5, the last quinquennial mean. The disease was therefore unusually prevalent. South Canara was the only district which escaped with complete freedom, but several districts suffered slightly. It was especially prevalent in the districts towards the south-east of the Presidency; Tanjore (11·1), Tinnevelly (9·6), and South Arcot (4·4) suffering most severely; the districts of Trichinopoly (3·7) and Madura (3·5) coming next in order. Throughout the Presidency 13·8 per cent. of villages were attacked, but in the above-mentioned districts the per-centages were as follows:—Tanjore 55·6, Tinnevelly 56·7, Trichinopoly 40·7, South Arcot 33·4, Madura 9·2. The disease caused the largest number of deaths in January, and thereafter the numbers rapidly subsided until the minimum was registered in April. Deaths then began to rise again in number until July, when a second subsidence occurred lasting until October. Thereafter a final recrudescence occurred, and during December the

number of deaths became again almost as numerous as they had been in January. As usual, mortality in towns was greater than in districts, the ratios being 5·3 and 2·5 respectively. Regarding the prevalence of cholera in the Tanjore district, it is stated in the Annual Report of the Sanitary Commissioner for Madras that—"The conditions "of soil and water in Tanjore are very similar to those in Lower Bengal, where cholera "is endemic though the climatic conditions of Bengal and Tanjore vary considerably. "Experience shows that in every new epidemic of cholera the disease will linger longer "in Tanjore than anywhere else. . . . . I believe that the habits of the people "and their mode of life in the delta portions of the district largely contribute to the "up-keep of cholera in their midst. They live in the midst of irrigated lands, and "when the rivers have dried up, take very little care of the drinking water supplies. "While the district is a wealthy one regarding its agricultural produce, the actual "labourers are very poor and live in wretched hovels built on a damp porous soil. "The cause of the continued prevalence of cholera in the Tanjore district was most "probably owing to the peculiarly contaminated water-supply upon which the people "are dependent. And the peculiarity of the water-supply and the habits of the people "favour in every possible way the propagation and retention of the disease. The beds "of these water-courses in the dry weather are used as *places d'aisances;* but when "they contain water, the banks are used, and the individual proceeds at once to wash "his person in the water. These water-courses feed the tanks, and on these tanks the "people in almost all the towns and villages of Tanjore depend for their drinking "water."

Cholera in Bombay Presidency was considerably less prevalent than in 1883. It gave rise to 13,804 deaths, or 24,150 less than in 1880, and 11,585 less than the mean of the preceding 10 years. It prevailed epidemically in two separate portions of the Presidency: (*a*) along the coast districts from the Gulf of Cambay to the southern districts adjoining the Madras Presidency, extending there in area and involving all the districts of the southern registration circle, namely, Belgaum, Dharwar, Kaladgi, and Kanara; (*b*) along the Indus valley. These two epidemic areas are separated by Kutch. The total mortality of the year throughout the Presidency represents 0·84 per 1,000 of population, the mean of the previous 10 years being 1·56. In only nine previous years since 1866 has the mortality been lower than during the year under report. The disease prevailed most severely in the districts of the southern registration circle already mentioned, but especially in Dharwar, where 4,655 of the total number of deaths were recorded, equal to 5·27 per 1,000 of population. In this district 33 per cent. of villages were affected, but throughout the Presidency only 5·78 per cent. of villages suffered. After enjoying an almost entire immunity since 1879, Sind was again visited by the disease, only two of its districts, namely, Thar and Parker, escaping without any deaths. Throughout the Presidency the mortality among those attacked was 52·93, but this ratio ranged from 36·5 in Kaira (Gujarat) to 79·3 in Hyderabad (Sind). In Dharwar, where the disease was severest in incidence, the ratio was 51·2.

In connection with the occurrence of cholera on board ships at sea, an outbreak of the disease among coolie emigrants from Calcutta to St. Lucia presents some features of interest. Among the coolies collected together at the Calcutta coolie emigrant depôt previous to embarkation on board the steamship *Bracadale*, one child was seized with cholera and died on the 29th May. In consequence of this the embarkation of the coolies was delayed four days. No other cases having occurred, and no indications existing of any further threatened attack, the ship sailed on the 4th June with 650 souls on board for St. Lucia, including the parents and relatives of the child who had died of cholera. The steamer is described as a fine vessel, very clean, and with excellent accommodation. She experienced rough weather in the Bay of Bengal, where even the water closets could not be cleaned, and arrived at Colombo on the 11th, and on that day a child who had been suffering from diarrhœa since the 8th, died. The case was not at the time recognised or recorded as one of cholera. On the following day, the 12th, another child died while the ship was still in harbour. This case also was not entered on the Register as one of cholera, and the vessel sailed that day for the Cape of Good Hope. On the 13th, another child died after a few hours of illness, and from that date till the 10th July, when the epidemic ceased, there were amongst the emigrants 23 cases and 19 deaths. The first adult coolie was attacked on the 21st. There were thus in all 25 cases among the emigrants as follows:—

7	cases and	6	deaths	among male adults.
4	„	4	„	female „
14	„	11	„	children.

Of these 14 children, one was four days old, two were 18 months, five were three years of age, two were four years, one was six, one was seven, one was eight, and one was ten. The earliest cases were first entered as diarrhœa, and the name subsequently changed after the disease had become distinctly unmistakeable. But assuming that they were all undoubtedly cases of cholera, the first case began with ordinary diarrhœa three days after the vessel left Calcutta, or 10 days after the death of the child from cholera at the depôt, and did not end fatally until the seventh day after sailing, or the 13th day after the death of the child at Calcutta. In the 18th Annual Report of the Sanitary Commissioner with the Government of India, no less than eight cases are recorded in which cholera broke out on board emigrant ships after being more than 20 days at sea. The ship arrived at St. Lucia in the first week of August, and the passengers and crew were immediately put in quarantine, and whilst thus segregated many deaths occurred among them from other diseases, showing, in the words of the Protector of Immigrants there, that "this was a wretched sickly lot, steeped in the "disease of vice with all its baleful consequences."

In conformity with the practice followed in previous years, extracts are given in the following paragraphs from the reports of Medical Officers on the circumstances attending outbreaks of cholera which came under their observation.

Amongst British troops in six instances a history of indiscretion in eating or drinking is given as attending the first cases. In one of these cases it is stated that the patient in the evening, previous to attack, "gorged himself in the coffee shop, having eaten largely "of curry and rice, which he washed down with copious draughts of tea and followed "up with a number of buns. He had not been subjected to any fatigue nor exposed "to the weather. A case of cholera occurred in the town on the 13th April, or six "days previously, in a part which this soldier is not likely to have gone to." In three instances the first persons attacked were in hospital under treatment for other complaints, or had been but recently discharged from hospital. In one case which occurred in Calcutta the patient was a recruit, who had been a tea planter, but who for several weeks previous to enlistment had been living in Calcutta under great hardships and privations. In six instances a previous history of physical fatigue is given, but in most cases this was not by any means of an excessive kind. Among Native troops nothing of consequence in this respect is related. Soldiers are of course often on duty involving a certain amount of fatigue prior to attack, and accordingly we have several such instances recorded, but no particular hardship or exposure is instanced. Among the prisoners of India, in 23 of 28 jails affected, no unusual antecedent fatigue was noted. One prisoner was attacked while recovering from dysentery, and three a few days after discharge from hospital, where they had been treated for other diseases. At the Meerut Central Jail, where 28 cases occurred in all, it is stated that the first man attacked was of poor physique and very subject to fever. He had been working at a brick-kiln, and the second case occurred also in the person of a man similarly employed.

In the great majority of cases diarrhœa was not prevalent either among British or Native troops during outbreaks. Of 26 communities of British troops attacked by the disease, in 21 diarrhœa was stated not to have been prevalent. In one case only it was noted to have existed to a considerable extent. Among Native troops only five of 21 communities were affected with diarrhœa to some extent. On the other hand, among prisoners diarrhœa was usually prevalent at the time of outbreaks. At Meerut the Medical Officer reports that "there was no special prevalence of diarrhœa before "the outbreak, but during its progress, especially towards the close, it became very "common, severe, and alarming in connexion chiefly with fever or running into "dysentery." At Akyab, where 30 cases occurred, diarrhœa was very prevalent.

As regards British troops, complete information regarding the number of buildings occupied by affected communities and the number of these furnishing cases is not given, but accurate information is afforded in the case of 317 buildings occupied by such communities, and of these 51 furnished cases, equivalent to 16 per cent. This is a smaller ratio than that of the previous year, which was 21 per cent. In the Native Army the number of buildings occupied by affected communities was 2,228, of which only 39, or 1·7 per cent., furnished cases, against 2·3 per cent. in 1883. Among jails, of 473 buildings thus occupied, 67, or 14 per cent., furnished cases, against 18·2 per cent. in 1883.

No special atmospheric condition is associated with the appearance of cholera. The weather is described variously as hot, sultry, still, cloudy, &c., or again as wet and damp. At Allahabad, in connexion with an outbreak in September in the J.-2 Royal Artillery and Det. D. L. I., it is noted that a few days before the outbreak very heavy

rain fell, nearly four inches in 24 hours—a most exceptionally heavy fall and quite unlooked for. Medical Officers in charge of Native troops report stormy weather with thunder and lightning in three cases, rain in three, and damp and cloudy weather in three.

Accurate data are available regarding the number of attendants who came in contact with 182 cases of cholera in the British Army during the time they were being treated, namely, 364, and of these two contracted the disease, equivalent to 0·55 per cent. Of the two attacked, one, a medical officer, was one of six attendants on two cases at Fattehgarh, and the other was one of six attendants on three cases at Khandwa. No special reasons are given in the first case for supposing that the attack was due to contact with the patients. In the second case, the wife of a patient, the medical officer writes that she "contracted the disease from her most devoted attentions to her "husband." It should be noted that at Meerut and in the 2nd North Staffordshire Regiment marching from Quetta to Karachi, where the largest number of cases, occurred, not a single attendant was seized with the disease. At Meerut 39 people attended upon 56 cases, and in the marching regiment 30 attended upon 48 patients. Among Native troops 277 persons attended upon 66 cases, and not one contracted the disease. The largest proportion of attacks amongst those attending upon sick persons is recorded in the jail population. The conditions of jail life involving the aggregation of as many persons as possible within a small area, and exposing them all to like influences, would lead us to expect such a result. In jails 163 cases occurred and 252 attended upon them. Of these, seven got the disease, equivalent to 2·78 per cent. of their numbers. One victim was one of five attendants on 17 cases at Rajshahye, another one of 16 on four patients at Bogra, and with reference to this the Medical Officer writes—"I do not believe that he got the contagion, but I attribute his illness to the fact "of his taking a large quantity of food." At Cuttack one attendant of 12 on four patients got the disease: he was a sweeper employed in the garden who assisted in carrying and burying the excreta of the first case and was attacked five days afterwards and died. At the Meerut Central Jail two attendants of 13 were attacked, and at Akyab one of five; but no explanation is offered of these seizures. These results are brought together in the marginal table. It will be observed, that taking them altogether only 1·00 per cent. of attendants was attacked.

—	Number of Cases of Cholera treated.	Number of Medical Officers, Attendants, &c.	Number of these attacked with Cholera.	Percentages of Attendants attacked.
European troops	182	364	2	0·55
Native troops	66	277	0	0·00
Jails	163	252	7	2·78
Total	411	893	9	1·00

In most cases no sanitary defects of any consequence could be detected as possible sources of the disease among British troops. At Dinapore it is stated that "for some "time before the outbreak there was a considerable quantity of fruit for sale in the bazars, "and it is supposed the men partook of that freely." At Gwalior the "foul condition "of the tanks within the fortress" is again complained of, and it is further noted that "at certain seasons of the year soakage into the wells for drinking water after "heavy rain and faulty system of conservancy and sanitary condition of the surrounding "cities of Gwalior and Lushkar" are notable defects. With reference to the outbreak of cholera in the 2nd North Staffordshire Regiment marching from Quetta to Karachi, the Medical Officer reports that "all the camping grounds in the Bolan Pass were in "an unsanitary condition, a quantity of refuse matter being scattered about." Among jails in most cases no sanitary defects could be found. At Arrah the water of two large jail wells was found to contain an excess of chlorine and inorganic solids. At the Meerut Central Jail "the surrounding ground is low-lying and outfall small. It is "therefore not easily drained; the parade grounds in cantonments had been well "manured for grass growing; and as the jail lies low, most of the drainage from it "must pass by way of the jail.

The effect of movement of affected bodies into other though near localities was as usual most beneficial. Among British troops, cholera appeared in 26 communities, and in 15 of these movements were made into camp, in three to different barracks, and in eight the disease occurred in an isolated form and no movement was considered necessary. In 10 of the 15 movements into camp no further case occurred after movement. At Allahabad, where 19 cases occurred in all, only one man was attacked after the affected community moved into camp. Only at Meerut was the result of movement not so strikingly apparent. In this station the affected men were broken up into five parties which each moved into separate camps. In one party nine cases occurred in three different camps, and in another four cases in two camps, but the three remaining parties escaped without further attack. Amongst Native troops nine

of 21 affected communities moved into camp, and in only one of them a single case occurred after movement. Among prisoners movements were made only at Meerut and at Akyab. In the former place only two cases occurred after movement, although this was attended by much discomfort owing to heavy rain. The history of the epidemic at Akyab is especially interesting in this respect as well as in others: the Medical Officer writes:—"On the appearance of the first cases of cholera in the jail "it became a question whether it would be advantageous to the prisoners to take "them from the jail, wherein they had for two months been secure from cholera "(notwithstanding the prevalence of the disease in the town), and locate them outside "the jail in an area which had been affected with the disease for that space of time; "to move them beyond the affected area was impracticable. And this question with "a rider suggesting that barracks should be constructed, but not occupied unless the "disease increased, was submitted to the Inspector General of Prisons, who replied "that no delay whatever should take place in the matter of removal, but that two-"thirds of the prison population should as soon as possible be moved into camp. The "result justified the expediency of this decision, for no sooner had the removal been "commenced and the jail population thereby thinned, than the disease began to abate "and speedily became altogether arrested; while of the prisoners who were camped "out not one was attacked. . . . On the expiration of 10 consecutive days "without the appearance of any fresh case of the disease, the return to the jail of the "prisoners camped out commenced, and by the 5th of November the entire convict "population was again within the jail walls."

Small-pox was generally very prevalent throughout India. It gave rise to 332,904 deaths, against 232,363 in 1883, a year itself of unusual prevalence of the disease. The largest number of deaths took place in the North-Western Provinces and Oudh, where no less than 202,541 of the total number of deaths were recorded, yielding a ratio of 4·59 per 1,000 of population. Such a mortality in these Provinces has not been recorded in any year since 1870. Its severity was mainly confined to the districts of Oudh. Of the total number of registration circles, 82 per cent. returned deaths from this cause and 40 per cent. of villages. Whilst the district mortality equalled 4·75 per 1,000, town mortality was only 2·18. The Madras Presidency suffered the next most severely from this disease. It recorded 61,247 deaths, or 23,272 in excess of the total number of 1883; or in other words, the mortality of 1884 was 2·1 per 1,000 against 1·3 during the previous year. Both ratios are unusually high, as the mean ratio of the previous five years (including 1883) was 0·7. The disease was very widely diffused over the Presidency, as no less than 226 circles of registration out of 229 recorded deaths. Rural and urban ratios were remarkably alike, the former being 2·1, the latter 2·3 per 1,000. The Province of Bengal recorded the next highest aggregate number of deaths, though it does not stand next in proportionate mortality to population. In all, 18,533 deaths were caused by this disease against 9,714 in 1883, or 0·28 per 1,000 of population, against 0·14 in 1883. Deaths were recorded in 53 circles, or in 2·96 per cent. of villages against 1·73 per cent. in 1883. The disease gave rise to proportionately greater mortality in towns than in villages, for whilst urban mortality equalled 1·10 per 1,000, in rural circles the ratio was 0·24 per 1,000. The disease was most prevalent in Gya, Sarun, Patna, Chumparan, and Hazaribagh. As usual, the mortality was chiefly borne by infants and children, as 72·27 per cent. of the total mortality from small-pox was contributed by them. In the Punjab, also, mortality from small-pox was greater than during the previous year; but the ratio of 1884, namely, 0·87, is below the average of the preceding five years, which was 0·94. Here the urban mortality exceeded the rural, the ratios being 1·07 and 0·86 respectively. In the Bombay Presidency the disease gave rise to a mortality (0·88 per 1,000) almost equal to that of 1883, but about four times as great as the average of the preceding five years, namely, 0·21. In British Burma the disease prevailed with unusual intensity: it gave rise to 6,102 deaths against 675 in 1883; but the latter year was one of unusual quiescence of the disease. Although causing a large loss of life, it was not widely diffused over the Province, as deaths were reported only in 1·20 per cent. of villages. In the Central Provinces the disease was more prevalent than in any of the three preceding years, giving rise to 4,882 deaths, or 0·55 per 1,000 of population. But this ratio is below the mean of the preceding five years, which was 1·04. In Assam, Berar, Mysore, and Coorg it was less than in 1883. Small-pox.

Fevers gave rise to 3,306,285 deaths against 2,879,659 in 1883; but the latter year was one of diminished prevalence of the disease. The aggregate number Feve

of deaths and ratio of mortality were less in Assam, Central Provinces, Berar, and Coorg than in 1883; in all the remaining provinces they were higher. Of the districts showing a diminished mortality the Central Provinces and Berar are the most conspicuous, and these also showed a remarkable diminution in the prevalence of cholera, as already remarked in a foregoing paragraph. Of the provinces showing an increased mortality the North-Western Provinces with Oudh and the Panjab stand forth prominently. In the former, fevers gave rise to 243,839 deaths in excess of the number of 1883, but the ratio per 1,000 of population for the year under report, 24·35, compared with the mean ratio of the previous five years, 25·54, shows that fevers were not unusually prevalent. In the Punjab the total number of deaths in 1884 exceeded the total of 1883 by 159,371, and the ratio per 1,000 of population of 1884, namely, 24·71, was unusually high, for the average of the preceding five years was 20·15. The disease was most prevalent in the Ludhiana, Umballa, and Karnal districts. It was not until September that a marked rise in mortality was observable, and the maximum number of deaths was reached in October. Fevers gave rise in Bengal to a larger mortality, both aggregate and proportionate, than in any previous year since 1871 when records were first kept. In all, 966,233 deaths were attributed to this cause, against 913,766 in 1883, or 14·60 per 1,000 of population, against 13·81 in 1883, or 12·38, the mean of the previous five years. These increased numbers for the year under report are attributed to improved registration. This may be so to a certain extent, but registration in this Province has not made much progress of late years. The disease was more diffused than during 1883, 64·78 per cent. of villages having recorded deaths, against 57·37 in that year. Although fevers were more prevalent in British Burma during 1884 than during 1883, yet the mortality ratio of the former year, namely, 8·08, differs but little from the average ratio of the previous five years, namely, 7·89. In the Madras Presidency the ratio of mortality, 7·6, is identical with the last quinquennial average. In the Bombay Presidency also the ratio of 1884 is practically the same as the average of the last five years, which is 16·09.

Bowel complaints.

The total number of deaths from bowel complaints, 274,234, exceeds that of the previous year, which was 261,623. The ratios of the present year do not differ much from those of the preceding one except in Berar, where it is only one half, and in the Central Provinces, where also there was a considerable reduction in the number of deaths from these causes. These two provinces, showed also the largest diminution in the number of deaths from fevers. This parallelism between fever and bowel complaint mortalities is not uncommon, and has been noticed in former reports. The seasonal prevalence of these complaints varied in the several provinces; but for India as a whole, July, August, and September are the months during which the largest number of deaths take place.

Injuries.

Injuries give rise to a somewhat larger number of deaths than in 1883, 76,583, against 76,059. The Central Provinces, North-Western Provinces with Oudh, Berar, and Madras, gave rise to the largest number of deaths from accidental causes in proportion to population.

All other causes.

In the report for 1883 it was noted that a progressive increase in the total number of deaths ascribed to causes other than those above considered had taken place since 1881, and it was thought that this indicated a more careful separation of deaths under their proper causes. The result of the year under review supports this view. The total number of deaths included under "other causes" was 953,141, against 889,243 in 1883. If the increasing number of cases recorded under this head be really indicative of improved and more careful registration as supposed, then the results in the Madras Presidency, Punjab, and Burma show improvement as compared with 1883.

Vaccination.

The largest proportion of population successfully vaccinated was recorded in Coorg, where 47·05 per 1,000 are stated to have been protected from small-pox. The next highest ratios were recorded in Berar (37·0), Central Provinces (36·01), and Bombay (30·39), and the lowest in North-Western Provinces and Oudh (12·88) and Burma (19·95). Comparing the protections protected during 1884 with the average annual successful vaccination during the previous five years, the result in the North-Western Provinces

with Oudh alone is unfavourable: in every other province an increased protection has been afforded, though in most cases to a small extent. Estimating the birth-rate at 40 per 1,000 in all provinces, the percentages of births successfully vaccinated were greatest in Berar (72·8), the Punjab (54·4), Bombay (43·9), and Central Provinces (44·3), and lowest in Burma (6·5), Assam (7·0), and Madras (10·8). In Bengal also the ratio was small, namely, 11·1 per cent. In Berar, each vaccinator of the special vaccination establishment performed on an average 2,175 operations, and in the Punjab 2,068. These are the highest averages, whilst the lowest were recorded in Madras (968) and North-Western Provinces and Oudh (987). The greatest success in primary operations was attained in the Bengal Province, where this was equivalent to 99·66 per cent. In most provinces primary vaccination was successful in over 90 per cent. of cases. In re-vaccinations success varied from 15·8 per cent. in Berar to 72·24 in Coorg, or 71·27 in Central Provinces.

In Bengal Proper the prejudice of the people against vaccination is gradually disappearing, and considerable progress has been made in the working of the department. During the year the Compulsory Vaccination Act was extended to several new police circles and towns, and the total number of operations increased from 1,364,642 in 1883–84 to 1,488,296 in 1884–85. Of these 1,402,260 were performed by Government and licensed vaccinators, and 86,036 by vaccinators attached to municipalities, dispensaries, &c. Of the 1,391,598 primary operations performed by the paid and licensed establishment, 1,379,608 were successful, or at the rate of 99·66 per cent., and of 10,662 re-vaccinations 4,163 proved successful, or at the rate of 44·75 per cent. In the vaccinations carried on in municipalities, dispensaries, &c., the percentage of success in primary cases was 94·72, and in re-vaccinations 63·75 per cent. Of the total number thus protected 211,430 were infants under one year of age, and 978,171 were children between one and six years old. But the fact that by far the largest proportion of small-pox mortality was borne by infants and children shows that much still remains to be done for their protection. In the vaccination circles altogether 28·94 per cent. of the population were protected. A large number of operations was performed with bovine lymph either direct from the calf or by arm-to-arm transmission, and the result was, on the whole, satisfactory.

During 1884 the vaccination establishment of the North-Western Provinces and Oudh was strengthened by the addition of 23 vaccinators, and the total number of operations rose to 656,561 from 649,067 in 1883–84, but the average number performed by each vaccinator fell from 1,011 to 987. Primary operations numbered 641,143, and of these 563,864 were successful, or at the rate of 87·94 per cent. against 565,351, or 92·11 per cent. in 1883–84. Re-vaccination is not carried out at all in the first circle. The second and third circles performed 15,418 such operations, of which 4,508 only were successful, or at the rate of 29·23 against 26·96 in the preceding year. The small amount of protection afforded by vaccination during the year is attributed to excessive prevalence of fever and small-pox, defective lymph, and want of energy on the part of the vaccinators.

During 1884–85 the Punjab vaccination establishment was strengthened by the addition to the staff of a Native supervisor and five vaccinators; and the number of operators in dispensaries also increased to 31 from 28 in the previous year. The total number of operations, however, performed throughout the province fell to 583,498 from 633,062 in 1883–84. This decrease in work is attributed to the excessive prevalence of fevers in the autumn months. Of the total operations 544,493 proved successful, which shows that of the population of the province only about 28·9 per 1,000 were protected. In primary operations performed by vaccinators the success was at the rate of 94·78 per cent., in re-vaccinations 41·53; and in operations performed by the dispensary officials, primary operations were successful in the ratio of 91·38 per cent., and re-vaccinations to the extent of 46·79. In most districts primary operations were performed upon children under six years of age. The Compulsory Vaccination Act was in force in the Amritsar Municipality, but here the deaths from small-pox were far more numerous than in any other town of the province. The lymph used was human, partly imported and partly collected in the province. No attempt was made to raise animal lymph locally, as is done in some parts of the country.

During 1884–85 no actual opposition to vaccination was met with in any part of the Central Provinces. Although there was considerable falling off in the number

of operations performed by the dispensary establishment, there was marked increase in those effected by the Government staff, and the total number of vaccinations for the province stood at 415,804 against 410,121 in the previous year. Of these, 400,455 were primary operations, which proved successful in 385,659 cases. The per-centage of success in the vaccinations performed by the regular establishment was 96·56 per cent. in primary cases, and 71·27 in re-vaccinations. In the operations carried on by dispensary officials the success in primary cases was at the rate of 92·20, and in re-vaccinations at 75·00. The per-centage of success in primary cases returned by the vaccinators is probably exaggerated, as in those inspected by the Civil Surgeons or Native Superintendents it never exceeded 92. Compared with 1883–84, the inspection work done by the Civil Surgeons was less, but that done by the Native Superintendents was greater. In all, about 38·27 per 1,000 of the population of the province were protected by vaccination.

Under the reorganisation carried out in November 1883 the vaccination staff of Berar Province was reduced from 64 to 49 operators, but the number of Native Superintendents was raised from 6 to 7. These men were to carry out the work for 10 months in the year, instead of six months, as in previous years, and consequently, notwithstanding a decrease in the number of vaccinators, the results of 1884–85 show considerable improvement both as regards quantity and quality of work done. The operations performed by the special establishment amounted to 93,517, or 14,313 more than in the preceding year. All these, with the exception of 82, were primary vaccinations, and the per-centage of success among them was 95·3 per cent. against 92·9 in 1883–84. Of the 82 re-vaccinations, only 13 proved successful, or at the rate of 15·8 per cent. Besides these, 7,617 operations were done by medical subordinates attached to dispensaries, of which 90 per cent. were successful in primary cases and 47·6 in re-vaccinations. In all, 37 per 1,000 of the population were protected, against about 30 per 1,000 in the previous year. The number of children protected under one year of age was 70,108, or considerably more than one half the total births of the year. The inspection work carried on by the Superintendents was also much more satisfactory than in previous years. Humanised lymph was kept up in all parts of the province, and in the districts of Akola and Amraoti animal lymph was also used to a certain extent.

During the year under report several Medical Officers in British Burma "took a "personal interest in, and worked hard for, the cause of vaccination;" and, in addition to the work done by the Government officials, a large number of vaccinations was also performed by missionaries in various parts of the country. A new district, under the name of Salween, with a population of 30,009, was for the first time brought under operation. This accession, together with the great increase of vaccinations which took place in the districts of Sandoway, Hanthawaddy, Prome, Amherst, Mergui, and Shwegyin, raised the total number of operations performed by the special establishment in 1884–85 to 89,923, from 73,269 in 1883–84. Of these, 82,805 were primary cases, and 7,118 were re-vaccinations with success at the rate of 84·3 and 65·9 per cent. respectively. The average number vaccinated by each vaccinator was 1,427, which varied from 176 in Toungoo to 4,921 in Sandoway. The failure at Toungoo has already attracted the Chief Commissioner's attention, and the Sanitary Commissioner has been directed to inquire into the matter. Animal lymph was successfully cultivated in Rangoon and Akyab, the former town supplying a large quantity to out-stations. In both these towns the Compulsory Vaccination Act was introduced, and byelaws under the Act have been sanctioned. As pointed out by the Chief Commissioner, it is very desirable that vaccinators should be closely watched to prevent them from practising inoculation, and that in future reports the number of successful operations, verified by the Civil Surgeons during their tours of inspection, should be shown. Although taken by itself, the result of dispensary vaccination in the year under review does not appear on the whole satisfactory, yet, compared with 1883–84, it indicates considerable progress. Of a total of 70,431 successful primary cases, only 9,753 were infants less than a year old, and 35,845 were children between one and six years of age.

The vaccination staff employed by the Government of Assam consisted of 169 operators against 170 in the preceding year, but it is satisfactory to find that the number of ex-inoculators who were suspected in former years of having practised inoculation under cover of their licenses was considerably reduced during the year. On the whole, the results of 1884–85 testify to steady and marked progress in vaccina-

tion as compared with the three preceding years. In some places, however, there was a considerable reduction in the number of operations performed; Sylhet and Cachar are examples of this, as also tea-gardens, the returns of which are, however, admittedly imperfect. The results in Sylhet and Cachar are rendered more unsatisfactory by the facts that the working staff in the former district was double that of any other in the Province, whilst in the latter the number of vaccinators was increased by two in the year under review. Of the total number of vaccinations performed durng the year, all but 583 were primary, and the average number performed by each vaccinator was nearly 564. Primary operations only were performed in tea-gardens, and in these the per-centage of success was 64·93. In similar operations performed by the district staff 91·78 per cent. were successful. Inspections were also carried out on a more extensive scale than in the previous year, 41 per cent. of the total operations having been verified during the year, against only 32 per cent. in 1883–84. The Compulsory Vaccination Act was in force in the Municipalities of Gauhati, Dhubri, and Sylhet, and in the Cantonment of Dibrugarh; but the results are still too meagre to warrant any definite conclusion being drawn as to the success or failure of the Act. It is encouraging to notice that the efforts of local boards in promoting vaccination were attended with success. The lymph supply was deficient, and in some cases inferior in quality.

During the year under review there was an increase of eight deputy inspectors and 38 operators to the vaccination staff of the Madras Presidency, and the number of operations rose from 749,038 with 687,175 successful cases in 1883 to 799,311 with 729,119 successful cases in 1884. Of these 133,856 successful cases were among children under one year of age. This shows that, deducting the deaths among children less than a year old, only about 19·5 per cent. of the infants born during the year were protected. Considering the extraordinary prevalence of small-pox, which caused a larger number of deaths than in any year since 1866 (with the exception of 1877), the protection of only 19·5 per cent. of infants and of 23 per cent. of the total population is to be regretted. The dispensary operations were successful at the rate of 79·7 per cent. in primary cases and 47·0 in re-vaccinations; but those performed by the other establishments combined had a per-centage of success at 93·0 and 54·3 respectively.

The average number of vaccinators employed in the Bombay Presidency during the year was 453, and the total number of operations performed by them amounted to 837,163. Of these 777,100 were primary operations with 739,393 successful cases, and 60,063 were re-vaccinations with success only in 39,128 instances. In addition to these, 25,871 operations were performed by dispensary officials. The total number of vaccinations in the Presidency, therefore, during 1884 was 863,034, of which 801,306 were successful. These do not compare favourably with the results of the preceding year, when the special establishment consisted of only 437 vaccinators, and the total number of operations was 878,312 with 823,200 successful cases. The extent of protection afforded was consequently less than in the previous year, the number successfully vaccinated per 1,000 of population in 1884 being 30·39, against 31·01 in 1883. The Compulsory Vaccination Act has been in force in Bombay city for the last seven years and in Karachi for five years, and in both places a large number of children was protected. In most parts of the Presidency vaccination was carried on with human lymph from arm to arm, in the Bombay town with animal lymph only, and in some places, such as Poona, Broach, &c., with both kinds. The number of operations verified was 88·44 per cent., against 40·76 in 1883.

The Vaccination Department of Coorg was remodelled during the year under report. It consisted of one inspector and seven vaccinators instead of one inspector and four vaccinators as before, and it is gratifying to observe that the work done by each one of the establishment was greater than before and of better result. The total number of operations, including those performed by medical subordinates attached to dispensaries, was 10,598 with 9,360 successful cases, equivalent to 88·3 per cent., against 5,330 and 4,596, or 86·2 per cent., in the preceding year. Of the persons protected by vaccination during the year, 900 were infants under one year of age and 4,020 were children between one and six years of age. The proportion of persons successfully vaccinated per 1,000 of population was 47·05, against only 22·64 in 1883–84.

In the British Army 849 men were primarily vaccinated with success in 636 cases, or 74·91 per cent., and in the Native Army 2,358 operations were performed, of which 1,579, or 66·96 per cent., were successful.

Sanitary Works—Military.

The following statement furnished by the Examiner of Accounts, Military Works, shows the particulars of expenditure on military works during the year 1884-85 :—

Military Works.

	Rs.
Original works	20,25,943
Repairs	17,61,009
Establishment	14,34,978
Tools and Plant	49,854
Barrack Department	4,78,246
Total	57,50,030

No information can be furnished as to the details of works executed or in hand during the year as the necessary data are not at present available.

Civil Sanitary Works.

Of the income of the Bengal Municipalities, 87·60 per cent. were expended on sanitary works in 1884, as compared with 34·48 in 1883. It was, however, very unequally distributed. While at Mokameh, Kishoregange, and Burdwan 55·19, 42·73, and 43·10 per cent., respectively, were laid out on sanitation; in places like Hooghly and the suburbs of Calcutta, notwithstanding their large income, only 0·77 and 1·24 per cent. were spent under this head. The principal items of expenditure were, as usual, conservancy, drainage, water-supply, vaccination, slaughter-houses, &c. Under water-supply the outlay of the year was less than 1883. The following were the important sanitary works carried out or taken in hand during the year:—The Burdwan waterworks were completed and formally opened in November 1884. Arrangements were made for the preparation of plans and estimates of an approved scheme of water-supply for Howrah and some of the other river-side municipalities between Howrah and Chandernagore. In Dacca, some improvements were made in the filter beds to prevent leakage, and the water-supply was extended northwards to Nawabpore road. In Bhagalpur, material and plant were being collected for carrying out the water-supply project already sanctioned by Government. The Sarun canal was improved at a cost of Rs. 20,000. Steps were being taken to improve the drainage of Ranigunge. In the city of Moorshedabad, the drainage works commenced in 1883 were completed, and further improvements are under consideration. Estimates and plans for a thorough drainage of the town of Dinagepur were under consideration. In the Midnapore district Rs. 88,600 were expended on the drainage of the *Supai Khal*. Further improvements were made in the drainage of the Nuddea district. Besides these, many sanitary improvements were carried out also in Calcutta and its suburbs. No particular attention seems to have been paid to the improvement of the sanitary condition of villages. In this respect, however, the suggestion of the Magistrate of Shahabad to the effect that Government ought to take special sanitary action in its own villages and assign a per-centage on the rents for the purpose seems well worthy of consideration.

In the towns of the North-Western Provinces and Oudh no sanitary work of any magnitude was executed during the year. Almost all the municipalities in the province devoted a portion of their income to sanitation, the expenditure in most instances being for the maintenance or improvement of existing arrangements in connexion with drainage or water-supply, and in some cases to original works, such as the sinking of wells, construction of masonry drains, culverts, latrines, &c. In the following instances large sums of money were expended on permanent sanitary works:—At Bareilly Rs. 26,004 were spent chiefly on works undertaken for the perfect drainage of the city site. At Saharanpur, a loan of Rs. 50,000 was applied for to carry out a complete drainage scheme for the city. At Meerut, Muzaffarnagar, Hapur, Sirdhana, and Mainpuri, drainage ways were made for effectually removing excessive rainfall from town sites. At Gorakhpur and Azamgarh considerable progress was made in extensive drainage works. A scheme was prepared for the water-supply of Lucknow, and the question of experimental artesian borings was under the consideration of the Government.

Of the sanitary works executed or undertaken during the year in the Punjab, the following were the most important:—At Simla the Sanjauli reservoir, calculated to hold about two million gallons of water, was so far advanced by the end of the year that water could be stored in it. A portion of the Simla drainage scheme, at an estimated cost of Rs. 1,11,345, was sanctioned, and during the year the pipe track was completed. At Amritsar, an extramural drainage scheme for the removal of storm water from the city and suburbs, and for the drainage of certain *jheels* near the civil lines, was in progress. A new scheme for water-works at Delhi, at an estimated cost of Rs. 10,10,279, was sanctioned. The drainage of certain suburbs of Delhi was taken in hand again at a cost of Rs. 15,000. The Bara river, which runs through the Peshawar city, was converted from a filthy channel into a clear stream fit for watering streets, &c. A scheme for supplying pure drinking water to the city of Peshawar was under consideration. Arrangements were made for the supply of pure water to the civil station of Dalhousie. Measures were under consideration for ensuring a pure water-supply to Kasauli. Besides these, minor sanitary works were carried out in all the districts. The total assets of the municipalities in 1884 amounted to Rs. 37,95,192. Out of this Rs. 9,43,989, or above one-fourth, were expended on sanitary works, including vaccination. The Sanitary Commissioner did much useful work by visiting various municipal towns in the province and endeavouring to impress upon the members of the newly elected boards under the Local Self-Government Act the necessity of scavenging their towns on a systematic plan, of futhering vaccination, and in drawing the attention of the public in general to domestic and personal hygiene.

No sanitary works of any magnitude were undertaken or executed during the year in the Central Provinces. Works of minor importance, such as cleaning tanks, wells, and drains, repairing, and constructing latrines, dustbins, &c., &c., were carried out in almost all the districts. The number of new wells constructed throughout the province during the year was 144. In municipalities, Rs. 2,50,803, or 34 per cent. of their total income, were spent on matters connected with public health. At Khandwa a new and more powerful engine was brought into use at the Rameshwar reservoir. With reference to the village conservancy rules recently passed by the Chief Commissioner, many villages were inspected during the year. In some of them it is stated that measures in connexion with pure water-supply, removal of carcases to some distance from inhabited sites, &c., are already being attended to. Some time, however, must elapse before a strict observance of the rules by the village people can be expected. Future progress in this matter will depend much on the interest in it taken by the local officers.

The total expenditure incurred on sanitary improvements in Berar during the year amounted to Rs. 1,57,066. Of these, Rs. 24,173 were spent in civil stations, Rs. 61,149 in municipalities, Rs. 33,053 in non-municipal towns, and Rs. 38,691 in villages. The principal items of expenditure were conservancy, drainage and water-supply. Of the sanitary works executed, or in hand, during the year, the following were the most important. The Kalapani tank, commenced in 1882 at an estimated cost of Rs. 3,02,646, which is intended to supply the town of Amraoti with pure water by means of pipes, was approaching completion. The works in connexion with the Hirgowan tank in the Amroati hills were completed at a cost of Rs. 18,523. The Pahora tank also in the Amraoti district was taken in hand at an estimated cost of Rs. 28,621. The Dhamangaon tank in Ellichpur district was finished at a cost of Rs. 13,490. In Melghat seven anicuts (weirs) were completed at an aggregate cost of Rs. 20,881. In Akola the restoration of the old tank at Janona, to supply Khamgaon with pure water, at an estimated cost of Rs. 96,524, was about to be completed; and pipes from the tank to Khamgaon have been already laid at a cost of Rs. 23,524. At Mardi a tank at an estimated cost of Rs. 16,621 was in progress.

There is not much to record under the head of sanitary improvements in Assam. Of the total income of municipalities, only Rs. 69,177 were expended on sanitary works, including medical relief, against Rs. 83,483 in 1883; and on both drainage and water-supply, the two most important of sanitary works, the outlay of the year was less than in the previous year. The only works of any importance undertaken were the Gauhati waterworks, which are still in progress, and the Goalpara drainage scheme, the main channels of which have been already completed. Minor improvements were carried out in several municipalities, such as constructing or cleaning wells and tanks, &c.

Nothing seems to have been done during the year to improve the sanitary condition of villages in British Burmah, nor were sanitary works of any magnitude undertaken in towns. An elaborate scheme for the drainage of the town of Rangoon, at an estimated cost of 170,346*l.*, or along with a supplementary high pressure water-supply, at 180,035*l.*, was under consideration. Rs. 12,880 were expended in constructing masonry surface drains at Rangoon. At Prome Rs. 1,24,283 were spent on the new water-supply works, which were nearly complete. At Pegu a general scheme of surface drainage was being taken in hand, at an estimated cost of Rs. 25,000. Sanitary works of a minor nature, such as provision of surface drains, latrines, &c., were carried out in most municipalities; and it is satisfactory to notice that the committees of all the larger municipalities were evincing much interest in improving the sanitary condition of their towns.

Of the total income of the municipalities in Madras Presidency, including Madras town, Rs. 11,29,368 were allotted for sanitary purposes for the year 1884–85, but of this sum only Rs. 8,41,328 were expended in the nine months ending 31st December 1884. No new work of any importance was undertaken during the year. All that was done consisted in repairing and cleansing tanks and wells, and in constructing and repairing latrines, drains, roads, dustbins, &c. In the local fund circles Rs. 3,72,946 were sanctioned for sanitary work, but up to the end of December 1884 only Rs. 1,97,457 were utilized in improving the sanitary condition of villages. The works carried out consisted chiefly of constructing and repairing wells, tanks, dustbins, latrines, drains, &c., and improving village sites, &c. The Government has already taken steps to impress upon municipalities and local fund circles the necessity of utilizing all allotments for sanitary purposes during the year for which they are sanctioned, and better results may be expected in future.

The total income of the Bombay municipalities in 1883–84 amounted to Rs. 29,86,674, and of this Rs. 6,60,806 were expended on conservancy arrangements. Although no work of any magnitude was executed during the year, yet a great deal was spent on drains, water-supply, latrines, roads, markets, and other works connected more or less with the improvement of the general sanitary condition of the different localities. The most important of them were the following: At Ahmedabad Rs. 1,639 were expended on drains. At Viramgam Rs. 1,488 on waterworks. At Broach Rs. 2,507 were spent on improving slopes, and Rs. 17,084 on roads. At Surat Rs. 1,157 were spent on latrines, and Rs. 9,899 for extending the public park. At Kalyan Rs. 1,367 were spent in improving Lendi tank. At Ahmednagar Rs. 2,012 were expended on waterworks, and Rs. 8,115 on markets. At Sangamner Rs. 1,911 were spent on latrines and urinals. At Poona Rs. 47,997 were laid out on markets, Rs. 2,767 on cremation ghâts, and Rs. 3,346 on new drains and sewers. At Sholapur Rs. 10,297 were spent on waterworks, and Rs. 1,660 on drains and sewers. At Bagalkot Rs. 4,926 were spent on roads. At Karachi Rs. 6,040 were expended on paving, deepening and cleansing roadside drains and gutters. At Hyderabad the drainage of Jayhakh and Khalian lanes, waste water drains of city services, and cleaning fort tank and Shah Kalam tank were undertaken. The principal items of expenditure for sanitary purposes in local fund circles were construction of new wells and tanks and repairing old ones.

No sanitary work of any magnitude was executed in Coorg during the year. In four municipalities small amounts were expended in constructing or repairing roads, drains, markets, &c. A scheme for the water-supply of Mecara was under consideration.

General Remarks.

Revised form of bill of health.

Under the orders of the Government of India, dated 21st January 1882, Medical Boards were appointed at the chief ports of British India to report weekly as to whether cholera was epidemic or not at these ports, and bills of health to out-going vessels were based on these reports. But as the Board stated simply that cholera was or was not epidemic, without giving the reasons which guided them in forming their opinion, it was thought desirable that something more than a mere statement of opinion should be recorded on their weekly reports. Accordingly, a revised form of certificate was introduced by order of Government, dated 31st July 1885, and it was notified that "Boards should not merely certify whether cholera is 'epidemic' or 'not epidemic,' but "should invariably give some brief description of the character and incidence of the

"disease at the time of report." When the Board certifies that cholera is "not epidemic" clean bills of health may be given in the following standard form:—

"BILL OF HEALTH.

"This is to certify that the ship is at the time of leaving this port in a satisfactory sanitary condition, and that no case of infectious disease dangerous to life exists among its officers, passengers, or crew.

"It is further certified that the town and port of are at present free from epidemic cholera, plague, yellow fever, and all other dangerous epidemic disease."

"*Dated* "*Health Officer of the Port*
"*The* *(or Port Officer).*"

Should cholera however prevail epidemically, the last report of the Medical Board will be attached to the bill of health, which is to certify only to the state of the ship and its officers, passengers, and crew, the last paragraph of the bill of health being omitted.

Absence of cholera at the Haj of 1884.

The complete immunity from cholera enjoyed by the pilgrims to Mecca during the Haj of 1884, together with a diminished prevalence of sickness generally, is most gratifying evidence of the beneficial effects of a stricter attention to sanitation. Vice-Consul Dr. Abdur Razzak in his excellent report on the health of the pilgrims pertinently remarks, with reference to the absence of cholera, that this will doubtless be attributed by some to the increased vigilance displayed by the Turkish authorities during the year in connexion with quarantine, but he proceeds to show that the result may with greater probability be traced to local natural and artificial causes. The sanitary condition of Mecca and Moona was greatly improved, surface cleanliness and conservancy having been carefully attended to. Moreover, the water-supply for the use of pilgrims at Moona was of much better quality. In former years the water drunk by the pilgrims was obtained from tanks, which were filled during the rains, and which at the time of the Haj had lain stagnant for some time. During 1884 these tanks were emptied before the season of the Haj, and the pilgrims were in consequence obliged to buy the cleaner water brought to them from the Zobeidah aqueduct. Slaughter sheds also were erected at distances from one another, instead of being aggregated together as formerly, and arrangements were made for burying the carcases of sacrificed animals, instead of allowing them to putrefy on the surface. The encamping ground was more openly occupied, a larger space having been available owing to the absence of Persian pilgrims, who had for some reason been prohibited attending the Haj. Together with this greater attention to the most elementary rules of sanitation, the weather was unusually favourable; heat was less and cool breezes prevailed at times. It seems, therefore, more reasonable to ascribe the immunity from cholera and the lessened prevalence of disease generally among the pilgrims to these causes than to look for an explanation of the absence of cholera in imperfectly conducted measures of quarantine. The futility of quarantine, even when enforced with every possible rigour, has been demonstrated time after time and has been admitted at the recent international conference assembled at Rome by some of the most advanced contagionists.

Pathological laboratory for special investigations.

The new laboratory, for the construction of which it was stated in the report for 1883 arrangements were being made, has been completed, and now affords facilities for special research in minute pathology. The great importance attached at the present time to germinal pathology rendered it desirable to equip the laboratory with the special apparatus and appliances necessary for researches in this domain. This has now been done. In the meantime, however, during the construction of the laboratory no time was lost in pursuing investigations into the relationship of cholera to Schizomycete organisms, commenced in Calcutta by the German Cholera Commission and continued by the English Commission. Dr. D. D. Cunningham, to whom this investigation was entrusted, has submitted an excellent report on the results he has obtained, which is published *in extenso* in a separate volume.

Scientific memoirs.

Papers on purely scientific subjects were in former years incorporated in the Annual Reports of the Sanitary Commissioner with the Government of India as appendices; but for many reasons it has been considered desirable in future to publish them

separately, the chief of these being that in such form they would be more readily accessible to workers on the subjects treated. The separate volume in which it is proposed to publish papers of purely scientific interest will be entitled "Scientific "Memoirs by Medical Officers of the Army of India." The first volume of what it is hoped will be a yearly series will be published contemporaneously with this report, and may be obtained at Rs. 2 a copy. The publication of such an annual volume will, it is hoped, stimulate Medical Officers interested in biology to work at any branch of this subject in their leisure hours, and afford them an opportunity of publishing the results of their labours. Hitherto it is feared that many officers may have been deterred from undertaking original research for want of a convenient channel of communication. Such a channel is now open to them and Medical Officers will be invited to submit contributions in any department of biology to the Surgeon-General with the Government of India, which, if considered of sufficient merit, will be published in this volume.

The observations on which Dr. D. D. Cunningham's report on the relation of cholera to Schizomycete organisms is founded were carried out during the course of the current year and dealt specially with the following points :—

I.—The association of curved Schizomycetes with materials of choleraic origin.

II.—The presence of similar bodies in other media.

III.—The effects of variations in the nature of the medium in which they are developed on the curved Schizomycetes, occurring in association with choleraic materials. The results arrived at were in accordance with those of other observers in regard to the presence of readily cultivable curved Schizomycetes as a characteristic and even, so far, diagnostic feature of the intestinal contents in cases of cholera. They further agree with previous observations in showing the absence of these bodies from the blood and tissues as examined and cultivated under ordinary conditions. With regard to the occurrence of such bodies elsewhere, it is shown that curved Schizomycetes of various forms, some of which are identical morphologically with the choleraic "commas," are constantly present in the intestinal contents during health, but that these differ from their choleraic allies in not being cultivable under the conditions favourable to the latter. Dr. Klein's observation on the normal occurrence of curved Shizomycetes in the intestinal contents of healthy guinea-pigs are also confirmed, and the frequent occurrence of similar organisms in the water of tanks in and around Calcutta, quite apart from the presence of cholera in the immediate vicinity, is also pointed out. The concluding part of the paper deals with a series of observations showing the extent of variability of form manifested by the choleraic "commas" under the influence of special conditions and corroborates Dr. Klein's statement regarding the occurrence of processes of multiplication in them departing from the ordinary type in the line of fissure being longitudinal in place of transverse to the long axis of the parent organism.

In this volume another paper will be found, "On the Presence of Peculiar Parasitic "Organisms in the Tissue of a Specimen of Delhi Boil," also by Dr. D. D. Cunningham. This is a valuable contribution to the pathology of this affection, forming a continuation of his report, written in conjunction with Dr. T. R. Lewis, "On Oriental "Sore," and published in the Twelfth Annual Report of the Sanitary Commissioner with the Government of India. The following is a resumé of the results obtained.

The "Delhi boil" is described as a simple granuloma, associated with, and very possibly due to, the presence of a peculiar form of parasitic organism. The essential feature in the diseased area is said to consist in an accumulation of lymphoid and epithelioid cells among the normal tissue elements. In the dermis these granulation cells open out and dissociate the normal tissue elements, but do not necessarily go on to the formation of tissue of an adenoid type. The real stroma of the neoplasm consists, therefore, not of any new formation, but of dissociated elements proper to the normal tissue of the part. With a view to ascertaining whether these morbid growths were associated with any special form of bacterial organisms numerous sections were made, and stained in a variety of re-agents. In all sections stained with gentian-violet, and in some stained with fuchsin, peculiar bodies were found to exist constantly in the masses of lymphoid elements. No other dyes affected them. These bodies, stained blue with gentian-violet, varied considerably in size; on an average $\frac{1}{2017}''$ × $\frac{1}{2360}''$; some are described as very minute, but, as a rule, they were considerably larger than the lymphoid elements among which they were situated. In

form they were circular, elliptical, or lobate, sometimes presenting a delicate cell wall, which was, however, at other times not discernible. The stain has a special affinity for the nucleoid bodies contained in these cells, which varied extremely in number. Some cells contained only a single great nucleoid mass, whilst others contained a few of various sizes, or large numbers of minute and fairly equal-sized ones. These cellular bodies were found to be distributed throughout the entire extent of the morbid tissue, but were found in great numbers, especially in the central parts of the continuous stratum of granulation tissue beneath the papillary layer. They were found also in specially large numbers in places where traces of hair follicles were recognisable. Though most numerous in these parts, they occurred also in the deepest parts in the subcutaneous tissues. No opportunities were afforded of obtaining an insight into the developmental history of these peculiar bodies, but Dr. D. D. Cunningham was inclined to regard them provisionally as representing various stages of some simple organism of Mycetozoic origin (probably parent plasmodia or amœbæ). Until their exact nature has been discovered, it is impossible to determine the relation which they may bear to the occurrence of the disease with which they were in this case associated. He writes:—

"There are, however, certain points rendering it possible, if not even probable, that they actually were the specific causes of the disease. In the first place, there can in regard to this specimen be no question of accidental entrance of the parasites into the morbid tissues due to abnormal facilities presented by the surface, for there was no ulcerated raw surface present, and, on the contrary, the horny layer of the epidermis was abnormally thickened and resistent. This in itself is in favour of a belief in their casual relation, as it is hard to see why such bodies should specially attain access to the diseased rather than to the healthy tissues unless some special structural facilities are provided in the former for their doing so. The general features of the distribution of the parasites also point in the same direction, for, as has been pointed above, they are found to occur in numbers varying in fairly close correspondence with the degree to which morbid changes have taken place. Much more significant, however, is the fact of their frequent presence in sites where such changes are only beginning to manifest themselves—in sites where small, isolated aggregations of the neoplasm are interpolated among wide areas of normal tissue elements."

On the whole, it is considered probable that these organisms may find access to the human body through water, and, considering the special numbers in which they are found in the remains of hair follicles and in the neighbourhood of sweat ducts, these structures may be regarded as special channels of access. "It is not claimed that these organisms, if they are the cause of the disease at all at Delhi, are necessarily always so; still less that all "Oriental sores" are caused by them. "All the changes "in the normal tissues," it is stated, "may be reasonably ascribed to mere persistent "local irritation of certain intensity, and it is quite conceivable that such irritation "may be connected with different exciting causes in different instances. Even, "therefore, should it eventually be demonstrated that all cases of such disease "occurring in and around Delhi are invariably and causatively related to the presence "of the parasitic organisms here described, it by no means necessarily follows that "all similar forms of disease occurring in other localities should have an identical "causation. It is quite conceivable that similar morbid changes may arise as the "result of the presence of other forms of parasitic organisms, or may even be "developed apart from parasitic agency of any kind whatever."

Sanitary Conference at Rome.

As these pages were passing through the press, the first volume of the Proceedings of the International Sanitary Conference at Rome was received. The Conference assembled on the 20th May 1885, and met but four times, appointing a technical committee to prepare a series of propositions to serve as a basis of future deliberation at plenary conferences. This first volume deals mainly, therefore, with the work of the technical committee. Notwithstanding the evidence frequently adduced elsewhere and emphatically reiterated at this conference itself, the proceedings of the committee show that the majority of representatives, especially those of Powers bordering the Mediterranean, still firmly believed in the importation from India, by way of the Suez Canal, of all the cholera epidemics which have visited Europe since that canal was opened. And, although there was an evident desire to diminish and mitigate the hardships and delays of quarantine as much as possible, yet there was a firm determination to impose restrictions on shipping from the East to Mediterranean ports at any cost. The most satisfactory feature in the proceedings of the committee is the

evident distrust evinced in the effectiveness of quarantine. Nevertheless, so disinclined were the majority of delegates to acknowledge its futility that the only index to their decaying faith in the measure is to be found in the substitution of the term "*observation*" for *quarantine*. The recommendations of the technical committee to be referred to the plenary conference at its next assembly as far as they interest India may be briefly summarised as follows:—

1. All land quarantine and sanitary cordons are useless.
2. As regards sea quarantine, five days' detention to be substituted for seven, hitherto the minimum in cases where cholera has occurred or is suspected to have occurred on board during passage.
3. The Indian ports will always be considered infected; yet quarantine will not be imposed unless the ship has had cholera on board after leaving port. An inspection by the Health Officer at a port within the Red Sea will be required, when if satisfactory proof be given that there has been no cholera and no grave suspicion of it, and that the ship is in a sanitary state, the ship will at once be granted "free *pratique*."
4. *Pilgrim traffic.*—The 10 days' detention at Camaran will be reduced to five, and this only when the ship is affected or obviously suspected; non-affected and properly equipped ships will, after an inspection of pilgrims on shore and detention of 24 hours for cleansing, be allowed to pass on at once to their destination.

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER FOR MADRAS FOR 1884.

(Deputy Surgeon General Geo. Bidie, C.I.E.)

European Troops.

The strength of Her Majesty's European troops belonging to the Madras Presidency in 1884 was 13,967.

Sickness and mortality among European troops.

The health of European troops, although disturbed by typhoid fever and cholera, was on the whole very good, and the death-rate lower than any on record in this Presidency. The admissions during the year were in the ratio of 1,106·1, while the average daily sick rate stood at 59·1 per 1,000 of strength, against 991·0 and 59·71 respectively, the rates in 1883. The mortality was reduced to the very low ratio of 8·5 per 1,000, a most satisfactory result considering the great prevalence of epidemic disease amongst the civil population.

The following table shows for a series of years the admissions, daily sick, mortality, and invaliding amongst European troops, and it will be noted that, while there has not been much reduction in the actual amount of sickness, there has, since 1880, been a decided decline in the death and invaliding rates :—

Years.	Ratio per 1,000 of Strength.			Invalided per 1,000 of Strength.	
	Admitted.	Daily Sick.	Died in and out of Hospital.	Change of Climate.	For Discharge.
1870	1,481·5	63·9	19·7	70·4	6·6
1871	1,211·5	56·2	19·1	29·7	12·5
1872	1,352·3	59·7	19·2	26·8	11·2
1873	1,270·8	59·3	18·5	50·6	12·7
1874	1,141·2	57·6	13·4	29·5	8·3
1875	1,096·3	56·9	14·8	60·3	15·5
1876	1,132·9	55·2	16·1	31·9	16·9
1877	1,172·2	58·7	17·2	36·0	10·2
1878	1,379·7	65·8	22·1	36·6	9·1
1879	1,438·7	68·4	16·8	34·3	10·2
1880	1,385·4	68·4	9·9	15·0	8·0
1881	1,164·8	68·2	11·1	18·6	8·8
1882	1,069·4	59·3	10·4	17·6	12·0
1883	991·0	59·7	10·0	20·1	13·6
1884	1,106·1	59·1	8·5	20·9	11·4

Excluding depôts and very small stations, the average daily sick rate per 1,000 of strength in the several cantonments ranged from 72·5 at St. Thomas' Mount to 33·6 at Thayetmyo, and the death-rate from 10·2 in Madras to 2·9 in Bangalore. The depôt at Wellington was fully utilized during the year by sending up young and feeble men likely to break down during the hot season, as well as invalids. Fevers and venereal diseases were the most common causes of inefficiency throughout the force.

There were 12 admissions with 10 deaths from cholera in the stations of Bangalore, Kamptee, Madras, Poonamallee, St. Thomas' Mount and Secunderabad, results which may be regarded as favourable considering the extent to which the disease prevailed amongst the civil population.

The chief incidence of small-pox was at Bangalore, where nine cases occurred with one death. Altogether there were 19 cases in the force against nine in 1883.

Fevers.—There were 762 cases of ague and 104 of remittent fever recorded. At Kamptee there occurred 379 cases of the former and 32 of the latter, and there were also a good many admissions under both heads at Secunderabad and Bangalore. During the past two years there has, on the whole, been a decline in admissions from intermittent fever. There were 129 cases of typhoid fever with 18 deaths, against 94 admissions and 29 deaths in 1883. The admissions in 1884 were, therefore, in the ratio of 11·9 per 1,000 of strength, and the deaths in the proportion of 1·6. As in 1883, the largest number of cases in any one station (60) occurred at Bangalore.

and there were 39 at Secunderabad and 15 at Kamptee. Bangalore is thus becoming notorious for enteric fever, a circumstance due no doubt to some extent to its impure water-supply. Fortunately this is at length to be remedied, as the subject has for some time engaged the attention of Government.

There were 602 admissions with four deaths from dysentery, against 513 and three respectively in 1883. The ratios per 1,000 of strength in 1884 were, therefore, for admissions 55·6, and for deaths 0·37. The admissions were most numerous in Secunderabad and Madras, and there was one death at each of the stations of Madras, Rangoon, St. Thomas' Mount and Tounghoo. Of diarrhœa there were 452 cases in the force with one death. The stations of Secunderabad, Bangalore and Thayetmyo show the largest numbers of admissions for this ailment.

The admissions under hepatic diseases were 310 and the deaths 23, against 422 and 17 in the previous year. The results for 1884 thus give an admission rate of 28·6 per 1,000 men and a death-rate of 2·1.

From sunstroke and heat apoplexy there were five deaths, four from the former and one from the latter cause.

Venereal diseases were more prevalent in 1884 than in 1883, the admission-rate per 1,000 of strength having been 256·1 in the former and 243·2 in the latter. The admission-rates for previous years shows a great amount of inefficiency due to this cause amongst British troops, and that all our efforts to improve matters have been of no avail. In the year under review the admissions were most numerous in Secunderabad, Bangalore, Madras, and Bellary.

Native Troops.

Sickness and mortality among Native troops.

The strength of the Native Army in 1884 was 30,623. These figures refer only to men serving within the Madras Command, Madras troops beyond its range being omitted, as no returns are received from them.

Native troops were not so healthy as in the previous year, the admission-rate per 1,000 of strength in 1883 having increased from 693·9, and the daily sick from 27·7 to 749·3 and 32·8 respectively in 1884. There was a slight decline in the death-rate as compared with that for 1883, although it still stands somewhat higher than the ratio for British troops. This disparity may be partly accounted for by the greater proportion of men somewhat advanced in years serving in the Native Army than in British regiments. The invaliding rate was 21·1, against 26·9 in 1883.

The following abstract gives the main facts connected with the vital statistics of Native troops for a series of years :—

Table showing the Admissions and Deaths amongst the Native Troops since 1868.

	Ratio per 1,000 of Strength.															
	1868.	1869.	1870.	1871.	1872.	1873.	1874.	1875.	1876.	1877.	1878.	1879.	1880.	1881.	1882.	1883.	1884.
Admissions	707·4	702·5	630·6	693·9	1,097·9	888·2	772·7	727·7	726·8	632·2	793·2	1,091·2	1,275·9	948·7	906·0	693·9	749·3
Daily sick	29·0	29·3	23·4	22·9	34·7	31·5	30·9	30·7	28·2	28·3	29·7	40·4	55·8	44·6	39·2	27·7	32·8
Deaths in hospital	8·6	10·1	9·4	8·8	9·9	6·4	7·7	9·0	9·8	11·3	11·7	11·8	12·3	13·2	12·4	9·6	9·0
Deaths out of hospital	1·4	2·6	3·6	1·3	2·4	1·6	2·0	1·5	1·2	1·7	1·6	2·5	2·6	3·0	2·6	2·3	2·6
Invaliding	16·4	24·5	25·6	23·3	23·4	30·9	33·5	39·5	37·1	30·5	29·6	36·9	31·6	47·0	39·0	29·0	21·1

The principal causes of sickness amongst Native troops were simple continued, and paroxysmal, fevers 6,861 admissions, skin diseases 2,776, dysentery and diarrhœa (655 + 532) 1,187, rheumatism 653, and respiratory diseases 605. There were also three cases of typhoid fever. The largest number of deaths (29) in the Native Army from a single cause was due to cholera; but respiratory diseases caused 28, remittent fevers 21, diarrhœa 21, and dysentery 16 deaths.

The total deaths from non-eruptive fevers amounted to 39 against 31 in the previous year, and the mortality was, therefore, in the ratio of 1·6 per 1,000 of strength, and 282·0 per 1,000 of admissions, from this class of fevers.

There were 66 admissions from small-pox and five deaths in the Native Army. Although the admissions in 1884 were more numerous than in several preceding years, they must be regarded as moderate considering the very great prevalence of the disease amongst the civil population.

From venereal diseases the ratio of admissions per 1,000 of strength in 1884 was 22·7, against 23·2 in 1883.

The health of the Native troops in the several stations varied greatly. Thus the average daily sick-rate per 1,000 of strength in the detachment in the pestilential climate of the Nicobars was 110·8, while at St. Thomas' Mount it was but 6·3. The stations, omitting small ones, at which there was the greatest amount of inefficiency from sickness were Tounghoo, Secunderabad, Rangoon, Moulmein, Cuttack, and Madras.

The station with the largest death-rate (23·3 per 1,000) was Tounghoo, and that showing the lowest, viz., 0·9, St. Thomas' Mount. Secunderabad had also a very high death-ratio, 22·7 per 1,000 men. There were no epidemics at Tounghoo to account for the great mortality, but 22, out of a total of 63 deaths, at Secunderabad were caused by cholera.

Cholera attacked the troops in the stations of Bangalore, Kamptee, Madras, Rangoon, Secunderabad, Thayetmyo, Trichinopoly, and Vellore; but the cases were few in number except at Secunderabad, where there were 41 admissions, and at Trichinopoly, where there were eight. The risk of cholera at Secunderabad is enhanced by the insanitary condition of the native town,* which is virtually overlapped by the cantonment, and by the unhealthy state of Chudderghat, as the native guard posted there, at the Residency, is very liable to attacks of the disease. In fact the duties assigned to our Native troops in that suburb of Hyderabad seem, in epidemic years, to be as perilous to life as a "forlorn hope," and this in spite of every practicable precaution for the protection of the men. The improvement of the drainage and water-supply of the town of Secunderabad is, however, engaging the attention of Government, and various important reforms are in contemplation. Small-pox appeared amongst the men in 14 stations, but with six exceptions only a solitary case in each occurred. In Bangalore there were 15 admissions from the disease, in Secunderabad 14, in Kamptee 12, and in Rangoon 11.

Jails.

Sickness and mortality in jails.

According to the figures of the Inspector-General of Jails, the prison population on the 31st December 1883 numbered 7,427, and during 1884 the additions to it amounted to 14,908, making a total of 22,345 against 24,200 in the previous year. During 1884 there was a decrease of 15,389 made up as follows:—

Liberated	12,713
Transferred to other jails	2,345
Do beyond sea	126
Escaped	6
Died	147
Executed	52
Total	15,389

The number remaining in confinement at the end of 1884 was thus reduced to 6,956 against 7,437 at the close of 1883, which is satisfactory as indicative of prosperity amongst the poor and labouring classes.

The sick admission-rate per 1,000 of strength of the entire jail population in 1884 was 769·5 and the death-rate 20·2, against 865·3 and 29·4 respectively in 1883. Contrasting the results of 1884 with those of a series of previous years, they were comparatively favourable. The death-rate in 1884 was, with one exception, lower than in any year since 1861–62.

The chief causes of admissions into hospital were intermittent fevers, skin diseases, diarrhœa, dysentery, and diseases of the respiratory organs. Contrasting the prevalence of these ailments with the results for 1883, there was an increase in diarrhœa and a fractional increase in respiratory diseases, but a decrease in the remaining causes of sickness.

There was a decided reduction in the deaths from some of the chief causes of mortality. Thus the death-rate from cholera was 0·9 per 1,000 against 1·9, from dysentery 1·2 against 3·8, and from diarrhœa 3·1 against 5·8 in 1883. Next to diarrhœa, the other diseases showing the highest mortality ratios are phthisis pulmonalis, other respiratory complaints, and dropsy.

* As regards drainage and water-supply.

Taking individual jails, the institutions showing the highest average daily sick-rates per 1,000 inmates are Kurnool (95·7), Chingleput (81·6), Her Majesty's jail, Madras (70·5), Tranquebar (60·6), Mangalore (57·8), Ootacamund European (57·2), Nellore (56·9), and Russellkonda (53·1). Looking at the death-rates per 1,000 of prison population, the highest are recorded against Rajahmundry District Jail (67·3), Tanjore (60·6), Cuddalore (59·1), Ootacamund Native (46·8), Coimbatore District (46·3), and Calicut (40·9).

Cholera appeared in the four jails of Cuddalore, Tanjore, Trichinopoly Central and Vellore Central. There were in all 24 admissions with seven deaths, of which 17 with five deaths occurred in Cuddalore jail. These results may be regarded as satisfactory, considering the great prevalence of the disease among the general population.

Small-pox caused 14 admissions and two deaths, and there were 69 admissions from chicken-pox.

In Chittoor jail, which was otherwise healthy, there were 220 cases of intermittent and 4 of remittent fevers, and the Medical Officer attributes their prevalence to the heavy rain and increase of wet cultivation.

In Chingleput, which is a small jail, the chief admissions were for skin diseases (39), diarrhœa (14), dysentery (5), and continued fever (9).

In Kurnool jail, which is also small, the principal causes of sickness were skin diseases (40), diarrhœa (12), and intermittent fever (8 cases).

In the Cuddalore jail the high death-rate was partly due to 5 deaths from cholera, but there were also 4 casualties from other bowel complaints and 1 from carbuncle. The Medical Officer, in referring to cholera, observes:—

"The first case occurred on the 3rd November 1884, and on the 4th there was another case, after which there was an interval of one week; on the 11th there were two cases, and up to 22nd instant 16 cases occurred and there was an intermission of twenty days, and thence again one case occurred on the 12th December 1884. On the 19th November 100 prisoners were, to relieve the main buildings, sent into camp jail."

The jail at Cuddapah enjoyed a wonderful immunity. Although the building is located in the centre of the town and cholera prevailed amongst the townspeople for a couple of months, not a single case occurred amongst the prisoners.

In the Ootacamund European jail the chief causes of admission into hospital were dyspepsia, diarrhœa, dysentery and fever. With regard to the native prisoners at Ootacamund, the Medical Officer says: "climate, with its daily extremes of temperature, is the main cause of the principal diseases, as diarrhœa, pneumonia, ague (in men already subject to it), bronchitis"; 16 cases of chickenpox, the origin of which could not be traced, also occurred at Ootacamund.

In the Penitentiary at Madras there were two outbreaks, aggregating 18 cases of chicken-pox, viz., one in the early part, and one towards the end, of the year.

Regarding Tanjore jail the Medical Officer remarks: "the general health of the population of this jail during 1884 has not been satisfactory. The prevailing diseases were dysentery, fevers and diarrhœa." There were 3 case of cholera, of which 2 proved fatal, amongst the prisoners, and the Medical Officer remarks: "No cause could be assigned for the occurrence of these cases." With the disease ravaging the general population on all sides, the only wonder is that the prisoners suffered so little.

In Trichinopoly Central Jail, which has for some time been remarkable for the great mortality amongst the prisoners, the death-rate per 1,000 of population in 1884 was 17·4. In 1880 the death-rate was only 33·6, but in 1881 it rose to 121·8, in 1882 to 162·5, and in 1883 it was 55·2. The sudden and alarming increase in 1881 was partly owing to an outbreak of cholera, which caused 84 admissions and 32 deaths, but the greater bulk of the unusual mortality was due to dysentery (44 deaths), diarrhœa (19), and dropsy (12), all diseases indicative, when unduly frequent, of defects in the food and water supplies. In 1882 the warnings of alimentary errors were still more pronounced, as out of a total of 143 deaths in the jail 119, or 83·2 per cent., were due to diarrhœa (58), dysentery (52), and dropsy (9). After much correspondence and inquiry, the prevalence of bowel complaints was ascribed to the use of badly-prepared and insufficient ragi rations. One remarkable circumstance connected with the outbreak of dysentery and diarrhœa was, that the female convicts, although using exactly the same diet as the men, escaped. This immunity was attributed to the women having managed to get better weight in drawing rations and to their being more skilful cooks than the males. With an improved diet and special care in other respects, the death-rate in the jail fell to 55·2 per 1,000 in 1883, and last year it was, as already stated, but 17·4. These results are so far satisfactory, but there are certain features in the history of the

extraordinary sickness which would seem to indicate that there was probably more than one cause in operation, and special attention should continue to be given to the water-supply as well as to the food.

In the six central jails the admission, average daily sick, and death-rates per 1,000 of inmates were as per margin.

Central Jails.	Admission-rate.	Average Daily Sick-rate.	Death-rate.
Cannanore	1,134·7	41·9	19·2
Coimbatore	490·1	17·6	24·9
Rajahmundry	1,227·1	40·1	17·1
Salem	718·3	19·5	7·6
Trichinopoly	385·4	15·5	17·4
Vellore	488·3	19·3	49·7

Rajahmundry shows high admission and daily sick-rates with a moderate mortality. The chief causes of sickness in this jail were intermittent fever (477 cases), diarrhœa (63), dysentery (27), dropsies (27), and respiratory diseases (20).

Cannanore also shows a large amount of sickness, but a low death-rate. The principal causes of admissions were intermittent fever (55 cases), diarrhœa and dysentery (53), respiratory diseases (21), rheumatism (23), and skin diseases 103.

The highest death-rate pertains to Coimbatore jail, but was not due to epidemic disease or any special cause.

The central jails were marvellously free from cholera, as only four cases occurred in the whole group, viz., two in Trichinopoly and two in Vellore.

General Population.

Vital statistics.

The important work of registration was still carried out as in former years, viz., under the supervision of the authorities in municipal towns and by the *karnams* in villages. As regards the statistics of the former, they are now fairly reliable, and the results from the latter also show signs of improvement. The duties of registration are, however, so mechanical and apparently purposeless to ignorant men, that they will only be made to realise their importance by the interest taken in the work by district officials when on tour, and by occasional inspections of the registers. The population figures are, in every instance in this report, those obtained by the census of 1881. The average population per square mile for the whole Presidency was 220·6.

The births numbered 827,381, and were in the proportion of 29·3 per 1,000 of population sending in returns against 27·7 in 1883. The birth-rate in 1884 was the highest on record in this Presidency, and is, it is believed, nearer to the true ratio than any hitherto obtained.

As in 1883 and previous years, the births in 1884 were fewest in the first and second, and most numerous in the third and fourth quarters of the year. Of the total children born, 423,108 were boys and 404,273 girls; so that 104·6 males were born for every 100 females. As already mentioned, the average birth-rate for the Presidency was 29·3 per 1,000 inhabitants, but the rates in the several districts ranged from 17·1 on the Nilgiris to 41·4 in Chingleput. On looking at previous returns, it is found that the average birth-rate on the Nilgiris during the past 10 years has been 17·1 per 1,000 of population. This comparatively low rate is no doubt, to some extent, due to imperfect registration, and perhaps to some extent to the rigors of climate; but I am credibly informed that it is common for low-country natives living on the hills to send their wives to the plains to be confined. With three exceptions, the births in the districts were more numerous than the deaths, the excess ranging from 19·9 per 1,000 of population in the conjoined districts of Bellary and Anantapur to 0·9 on the Nilgiris, while the mean excess for the Presidency was 6·2 per 1,000. The districts in which the deaths exceeded the births were Godávari, Tanjore, and Tinnevelly. In the Godávari district the excess of mortality amounted to 3·6 per 1,000 of population, and was principally due to the large numbers of deaths from small-pox and fevers. In Tanjore and Tinnevelly the disturbing cause was cholera, and the excess of deaths over births was 7·7 per 1,000 in the former and 3·5 in the latter district.

The deaths numbered 650,335, being at the rate of 23·1 per 1,000 of population against 19·0 per 1,000 in 1883. The increase in the death-rate was mainly due to the prevalence of epidemic disease, but partly to improved registration. The following table shows the mortality which has taken place during each of the past 16 years, and

excluding the famine period, it will be remarked that the death-rate was unusually high in 1884.

Years.	Population for which returns were received	Deaths.	Death-ratio per 1,000	Years.	Population for which returns were received	Deaths.	Death-ratio per 1,000.
1869	24,633,127	451,981	18·3	1877	29,209,542	1,556,812	53·2
1870	24,125,526	451,020	18·6	1878	29,122,205	810,921	27·8
1871	24,555,046	444,371	18·0	1879	28,991,267	549,390	18·9
1872	30,147,779	501,482	16·6	1880	28,778,097	454,101	15·7
1873	30,287,842	506,894	16·4	1881	28,676,375	465,682	16·2
1874	30,360,221	516,848	17·0	1882	28,887,111	470,700	16·2
1875	30,278,908	641,260	21·1	1883	28,503,100	541,930	19·0
1876	29,157,056	680,384	23·3	1884	26,151,952	650,335	25·1

There were 105·6 male deaths for every 100 deaths of females; or to put it according to population, the mortality amongst males was at the rate of 23·9, and amongst females in the ratio of 22·2, per 1,000. The death-ratios in the several districts varied greatly. Thus in Nellore and Ganjam it was 14·5 per 1,000, while in Tanjore it stood at 35·7.

The deaths according to age show a large infantile mortality, a sure indication of bad sanitation. Improper food and exposure are also causes of infantile sickness and mortality amongst the poorer classes, and large numbers of children perish from the great epidemics of the country. The total deaths for the year of children under one year of age amounted to 141,872, being in the ratio of 171·4 per 1,000 to the total births. From infancy up to 15 years of age females have obviously a better chance of life than males, but from 15 to 30 marriage and child-bearing reverse the state of affairs. From 30 onwards the females have again the superiority as regards expectation of life. These results are not only interesting as facts, but as a test of the approximate correctness of the statistics.

The statistics of deaths from the chief causes of sickness according to districts and towns of over 10,000 population show that in 1884 the death-rate per 1,000 was, from cholera 2·6 against 1·2, from small-pox 2·1 against 1·3, and from fevers 7·6 against 7·1 in the previous year. 1,514 persons committed suicide, of whom 870 were females and 644 males. 2,290 lives were lost by snake-bite and the attacks of wild beasts. Looking at the relative mortality to population in town and country it appears more than twice as many died from cholera in towns as in villages, and that small-pox was also slightly more fatal amongst the urban residents. Fevers, on the other hand, show a mortality of 7·8 per 1,000 in rural districts against 5·2 in towns.

The following abstract shows the chief causes of death for a series of years, and it will be noted that the great scourges of the population of Southern India, viz., cholera, small-pox, and fevers, were unusually active in 1884.

Years.	Total Deaths.	Cholera.	Small-pox.	Fevers.	Bowel Complaints.	Injuries.	Other Causes.
1866	600,106	200,961	23,106	110,102	—	9,047	256,890
1867	372,026	33,205	27,997	112,514	—	8,613	189,790
1868	390,959	8,036	34,330	105,692	—	9,242	233,659
1869	451,981	21,034	17,448	132,346	—	9,310	271,843
1870	451,020	55,867	11,252	151,027	—	12,325	220,549
1871	444,371	17,656	20,823	192,469	38,928	15,323	159,172
1872	501,482	13,247	39,074	214,148	39,387	15,150	180,476
1873	506,894	840	51,784	222,843	36,392	14,251	180,784
1874	516,848	313	48,348	226,220	37,993	13,065	190,914
1875	641,260	94,546	24,775	252,042	37,484	12,421	219,992
1876	680,384	148,193	23,469	230,992	138,176	11,175	229,279
1877	1,556,312	357,430	88,321	469,241	133,366	16,460	491,494
1878	810,921	47,167	56,360	374,443	48,083	15,007	269,861
1879	549,390	13,296	17,640	285,477	23,218	12,619	196,940
1880	454,101	613	14,529	209,940	19,622	10,845	198,552
1881	465,682	9,446	15,776	203,542	15,961	11,527	206,430
1882	470,700	23,604	20,159	188,561	19,958	11,611	206,807
1883	541,930	36,284	37,975	203,786	22,098	11,509	230,278
1884	650,335	75,476	61,247	215,977	28,775	11,502	257,358

The great epidemic of cholera which invaded Southern India in 1875 lingered till the close of 1879. Its final ravages were mostly confined to the northern districts, but by the month of December it had died out, and the year 1880 began with the large population of Southern India entirely free from the disease. Throughout the year only a few cases were reported and these chiefly from the northern parts of the Presidency. During the first three quarters of 1881 a similar immunity was experienced, except in the north, where there was a slight revival of the disease, but in October epidemic cases began to appear in Trichinopoly, Bellary, North Arcot, Salem, and Coimbatore. The year closed with cholera prevailing in all the districts south of Madras and with a total mortality of 9,446. In 1882 the disease continued to prevail in the southern districts, and also to some extent in Ganjam and Vizagapatam. The epidemic was most severe in Tanjore, Madura, Tinnevelly, and Trichinopoly, and the greatest numbers of deaths occurred in January, February, March and December. The total number of cholera deaths registered during the year was 23,604. In 1883 the disease had all but died out in the extreme north of the Presidency, and while it still continued very virulent in the south, it began to advance along the coast north of Madras and to show a tendency to invade the inland districts of Cuddapah, Bellary and Anantapur. During the last quarter of the year it was raging in Nellore, and had given the Kistna district a warning of its approach. In 1883 the mortality was greatest in the months of January, February, July, November and December, and the total deaths for the year numbered 36,284. The districts which suffered most were Tanjore, South Arcot, Tinnevelly, Trichinopoly, Salem and Coimbatore. Cholera.

Throughout 1884 cholera prevailed in all the districts of the Presidency except South Canara, which completely escaped. Its incidence in Ganjam, Vizagapatam, Kurnool and the Nilgiris was also very slight. Tanjore again bore the brunt of the epidemic, the cholera deaths in this unfortunate district for the year having amounted to 23,671, giving a death-rate of 11·1 per 1,000 of population. The long continuance of the disease in Tanjore and the heavy mortality caused much anxiety to Government, who accordingly invited the special attention of the Surgeon-General and of the Sanitary Commissioner to the subject. From the reply of the former it appears that during the last 18 years in which registration has been in force there has not been a single year without cholera deaths in this district, and the disease, he thinks, is "in some degree endemic in the locality." "The conditions of soil and water in Tanjore are," it is stated, "very similar to those in Lower Bengal, where cholera is "endemic, though the climatic conditions of Bengal and Tanjore vary considerably. "Experience shows that in every new epidemic of cholera the disease will linger "longer in Tanjore than anywhere else." The Surgeon-General further observes: "I believe that the habits of the people and their mode of life in the delta portions "of the district largely contribute to the upkeep of cholera in their midst. They live "in the midst of irrigated lands, and, when the rivers have dried up, take very little "care of the drinking water supplies. While the district is a wealthy one regarding "its agricultural produce, the actual labourers are very poor and live in wretched "hovels built on a damp porous soil."

Dr. Furnell, my predecessor as Sanitary Commissioner, paid a special visit to the district, and after his inspection stated it as his belief, that the cause of the continued prevalence of cholera in the Tanjore district "was most probably owing to the "peculiarly contaminated water-supply upon which the people are dependent." In describing the sources of potable water he says, "but the peculiarity of the water-"supply and the habits of the people favour in every possible way the propagation "and retention of the disease. The beds of these water-courses in the dry weather "are used as *places d'aisances;* but when they contain water, the banks are used, and "the individual proceeds at once to wash his person in the water. These water-"courses feed the tanks, and on these tanks the people in almost all the towns and "villages of Tanjore depend for their drinking-water. Moreover, not only are these "tanks filled with a water thus open to contamination, but they are themselves still "more polluted in every possible way. The women bathe, wash their clothes *and the* "*clothes taken from sick people* in them, and take home large, bright, clean chatties of "the filthy fluid to drink and cook with. At a meeting of the Municipal Commis-"sioners at Tanjore, I placed upon the table six samples of water taken from different "tanks in the town, and one sample of ordinary filtered drinking water from the house "of a European gentleman. The Native Commissioners could scarcely believe that "the green offensive fluids exhibited—one especially from the Iyenkulam—were "samples of the ordinary drinking-water of the people." He suggests that carefully conserved wells should be constituted for tanks, which are so liable to pollution, and

would even go a step further by having in the larger villages pumps to raise the water into reservoirs, from which it might be drawn by stop-cocks.

These observations of the chief medical and sanitary authorities appear to fully explain why cholera should be so severe and persistent in Tanjore. The general death roll of the Presidency will show how much has yet to be done to protect the people of Southern India from epidemic disease, and that our efforts must not be confined to periods when sickness is prevailing, but be continuous and systematic. Fortunately, too, the sanitary precautions which have been found most effectual in warding off cholera are equally valuable for the prevention of other diseases.

In offering these remarks, I have been placed at a disadvantage from not having been in charge of the office during the year, but this will be fully compensated for by the special report on the subject which Dr. Furnell has promised to submit.

Small-pox.

In 1884 small-pox prevailed in every district of the Presidency, and the mortality from it was unusually heavy. The death-rate was 2·1 per 1,000, a higher ratio since 1871 except 1877 when it reached 3·0 per 1,000.

The returns since 1871 show that the disease is subject to periods of repose and severe outbreaks. The latter do not appear to occur with any regularity, but are no doubt influenced by certain atmospheric states and any conditions that lower the vital powers of the general population. Where such a combination occurs—and there are at the same time large numbers of young people unprotected or imperfectly protected by vaccination—we have a severe outbreak, to be followed by a lull till similar conditions again occur. But the disease also varies in the malignancy of its type, as we know that in some of the former outbreaks in Europe it was almost as fatal in its ravages as the plague. Bad sanitary conditions are conducive to severity of type, and there can be no doubt that the malignancy of the epidemic in 1883-84 in Madras town, was aggravated by the crowded and filthy state of parts of Black Town.

Of the total deaths, 39,292—or nearly 64 per cent.—were in children under 12 years of age. The liability of the young to small-pox is still further illustrated by the results during the severe epidemic of 1883–84 in Madras town, as 74 per cent. of the total deaths occurred in children under three, and over 21 per cent. in children above three and under 12 years of age.

Excluding Madras, which only embraces the town and which will be specially referred to hereafter, it appears, that the disease was most severe in the Kistna and Godávari districts, the death-rates in these having been respectively 6·7 and 6·3 per 1,000 of population. Taking these results as a measure of the number of unprotected persons, vaccination requires to be energetically pushed in both these districts. Chingleput, South Arcot, Kurnool and Malabar show death-rates ranging from 3·2 per 1,000 in the two first named to 2·3 in the last. Of the total of 61,247 who died from small-pox throughout the Presidency, 31,296 were males and 29,951 females. The district in which the lowest death-rates occurred were the Nilgiris, Ganjam, Coimbatore, and Cuddapah. The disease was most prevalent and most fatal during the first seven months of the year.

In the town of Madras small-pox assumed an epidemic form in the two last quarters of 1883, and in the first quarter of 1884 it was so severe that Government deemed it necessary to appoint a Special Health Officer as a temporary measure, and to render the vaccination of children above three and under 12 years of age compulsory. During the first quarter of 1884 the deaths in Madras from small-pox numbered 3,157, and were, therefore, in the ratio of 7·7 per 1,000 of population. The outbreak reached its climax in March, in which month the mortality amounted to 1,256. In April there was a marked decline, and, by the close of the second quarter, during which 804 deaths occurred, the epidemic was practically at an end and public fear abated. As already stated, the disease was most destructive amongst children, and, as might be anticipated, it raged with greatest severity in the most crowded and dirtiest quarters of the town. Owing to native habits and prejudices, it is no doubt difficult to carry out in such cases the isolation of the sick, but in my opinion strenuous efforts should be made whenever small-pox invades a town or village to enforce this salutary measure. Such an arrangement in this country need not involve any great expense, as sheds or pavilions, with leaf or grass roofs and partial walls of matting, will meet all requirements. In the report of the Special Health Officer it is stated, "there was no attempt "at isolation in the houses of the affected, and persons suffering from all stages of the "disease might have been seen in the streets lying in the sun, and when convalescent, "but still centres of infection, moving about the crowded bazaars of the town or at "the railway stations." Under such circumstances and with a large section of the

population, especially the young, unprotected by vaccination or previous attack, it is not surprising that the disease was so prevalent and fatal. The total mortality in the town during the epidemic of 1883–84 was 5,284, or 13·0 per 1,000, and in 1884 the deaths numbered 4,064.

One good result that came out of the severe outbreak was the impulse which it gave to vaccination amongst all classes of the community.

Fevers.

As in the case of small-pox and cholera, fever was also unusually prevalent and fatal. The disease in some form was most fatal in the districts of Kurnool, Vizagapatam, Nilgiris, Cuddapah, South Canara, Ganjam, Malabar, Madras (town), Godávari and Kistna. In this group the highest rate of mortality was 15·1 and the lowest 9·0 per 1,000 of population. In the other districts the death-rates varied from 7·7 to 1·9 per 1,000. In 10 districts fever was more prevalent than during the preceding five years, and in the others less so. The total deaths from fevers during 1884 numbered 215,977 (111,246 males and 104,731 females), being at the rate of 7·6 per 1,000 of population. Fever was most fatal in the cold months of January, November, and December, but the deaths were also very numerous in the third quarter of the year. That a chill may develop an attack of fever is a well-known fact, but that there is a veritable malaria in most cases no one can doubt.

Bowel complaints.

The deaths from bowel complaints in 1884 numbered 28,775 against 22,098 in the preceding year. When cholera is epidemic bowel-complaints are more frequent than usual, but at the same time there cannot be a doubt that some deaths due to cholera are registered under the milder term. Even in military statistics, which are entirely in the hands of medical officers, a tendency is sometimes observed to avoid the more formidable name of cholera.

Deaths were most numerous in the months during which cholera was most prevalent. The districts showing the largest death-rates per 1,000 of population from bowel-complaints were Madras (town), Chingleput, South Canara, Malabar and Tinnevelly.

Injuries.

The deaths from these causes amounted to 11,502 against 11,509 in 1883, and were fewer in number than in any preceding year since 1880. In the year under review 1,514 are attributed to suicides, 861 to wounds, 6,837 to accidents, and 2,290 to snake-bites and the attacks of wild animals.

Vaccination.

During 1884 the operations of the Vaccination Department, past and current, were rigorously tested by the great epidemic of small-pox, which exhibited in many quarters an unusual malignancy of type and a corresponding infective power. Unfortunately we have no means of ascertaining the extent to which the protective influence of vaccination was manifested, but we may, from experience elsewhere, feel perfectly sure that it had the usual effect in restricting the spread and modifying the character of the disease, and in saving life. It would, however, be satisfactory at this stage of the history of preventive medicine in India, if we could collect some reliable data as to the actual value of our past vaccination operations. A good deal might be done in this direction if, in the case of admissions for small-pox into civil hospitals and dispensaries, the number and character of the vaccination marks borne by the patients, and the results of treatment as to death or recovery, were in each instance recorded. An inquiry of this nature would prove an efficient test, and in course of time would give us a large amount of valuable information, which sooner or later is certain to be required for public purposes. Vaccination unfortunately does not always confer the full protective influence which it is capable of exerting. To do this, the lymph must be good and the operation properly performed. Climate and protracted humanization exercise a deteriorating influence on the vaccine, while time reduces in the individual the amount of protection originally conferred, rendering a repetition of the operation necessary. Again, the number of arm-marks has a most important bearing on the validity of vaccination. An inquiry of the kind suggested would therefore, to some extent, show how far the conditions of thorough vaccination have been fulfilled amongst the general population; and, making allowance for the agency it has had to work with, and the obstacles encountered, I do not think that the Vaccine Department need shrink from the investigation.

That the people generally in India should be more or less averse to vaccination is hardly to be wondered at, considering that even in England it has been found necessary

to render it obligatory by law, and that, although there exist overwhelming proofs of its efficacy, there are people illogical enough to contend that it is valueless as a protection against small-pox. In fact the marvel is that the common people in this country are not more opposed to an operation which to some extent comes in contact with religious scruples, and of which the advantages are not always immediately obvious. Possibly their familiarity in some districts with inoculation with small-pox virus, has to some extent smoothed the way for the milder operation of vaccination. If we could only now get the educated classes of the native community to realize the inestimable value of vaccination, and to take an active interest in a matter of such consequence to all classes, the progress of the prophylactic would be much more satisfactory, and they would probably be the first to ask Government for some measure to render it compulsory.

I am old enough to have conversed with people at home who lived prior to the general introduction of vaccination, and who resided in a remote district to which small-pox inoculation had never penetrated: and there can be no doubt that Jenner's discovery was for some time regarded with nearly as much suspicion by the people at large in some parts of Great Britain, as it now is in India. And yet, at the time the conversation was held, vaccination was deemed as necessary for a child as the rite of baptism. We have no reason to despair therefore, I think, of vaccination becoming in due course more popular in Southern India.

There was an increase of two first-class deputy inspectors, six second-class deputy inspectors, and 38 vaccinators to the strength of the establishment, as compared with the numbers in the previous year. The augmentation in both the inspectorial and vaccinator grades was made, because the ranges in some districts were too large, or to meet the increased demands for vaccination due to the great prevalence of small-pox.

The total number vaccinated was 803,469 against 753,589 in 1883, making an increase of 49,880 in favour of 1884. Of the operations, 773,118 were primary and 30,351 secondary, so that the former were 36,456, and the latter 13,424, in excess of the corresponding results in 1883. The departments in which an increase occurred were Local Fund (26,598), Municipalities (16,538), dispensaries (9,339), and the Army (2,699). A great impetus was given to re-vaccination by the prevalence of small-pox. In Government, cantonments, native states, and medical subordinates the operations were less by 4,490, 393, 246, and 165 respectively.

The general rate of successful operations in 1884 was 91·2 per cent. against 91·7 per cent. in 1883. Taking primary and re-vaccinated cases separately, the ratio of success for the former was 92·6 per cent. against 92·7, and for the latter 54·4 against 46·4 in 1883. In primary vaccination the highest amount of success (97·1 per cent.) was obtained by Government vaccinators, and the lowest (59·0 per cent.) by medical subordinates. In cases of re-vaccination the greatest success (89·6 per cent.) was obtained in the European army, and the lowest (28·1 per cent.) again by medical subordinates.

Infantile vaccination continued backward, as the total number of successful operations performed by Local Fund and Municipal establishments was in the ratio of 15·4 per cent. on births, against 15·7 in 1883. The largest number of successful cases (375,687) was in children over one and under six years of age and in those above six years (204,658), but the latter shows a decline of 12,732 as compared with the result for 1883. Contrasting the work of establishments for the two years with respect to infantile vaccination, there was an increase under every head in 1884 except in the case of Government vaccinators.

Compulsory vaccination was brought into force in the city of Madras on the 23rd November 1884. Eight vaccine depôts were opened in various parts of the town to give the people the necessary facilities for complying with the terms of the Act. Supplies of lymph from calves were always available, and so far the results were satisfactory.

Sanitary Works.

Municipalities. No new work of an important nature was undertaken during the year in the Municipalities. All that was done consisted, as usual, in the repairing and cleansing of tanks and wells, and in the repair and construction of latrines, drains, roads, dust-bins, markets, slaughter-houses, &c.

Drainage, Water-supply and *Conservancy.*—No change has been made in these during the year. They were much the same as reported last year. The sources of water-

supply were the same, chiefly tanks and wells, and, in some municipalities, rivers and irrigation channels. Year after year greater attention is paid and care taken to conserve and preserve the sources supplying drinking-water from pollution. Generally speaking, there is no regular system of drainage. The existing drains consist chiefly of side-cuttings for surface drainage only. In some towns, however, pucka masonry drains exist. Cesspools abound and drainage from houses flows into these, or into the backyards, or into the streets, or into the side-cuttings. The system of conservancy was the same as last reported. The street sweepings, other refuse matters, and contents of latrines and dust-bins were removed daily by scavengering establishments maintained for the purpose, and carted away beyond municipal limits and disposed of as usual, either by burying in trenches, being thrown into fields, sold as manure, or consumed in cinerators.

On the whole it may be said that of late sanitation has made some progress in municipal towns. Much still remains to be done and there is ample room for improvement, but as we notice that the work done year after year is progressive, we may reasonably hope that the evils existing at present in many of the towns will be gradually removed.

The total estimated income of all the municipalities, Madras excluded, amounted to Rs. 19,27,462, which represents an incidence of Rs. 1-7-3 per head of population. The incidence in 1882–83 was Rs. 1-3-3 and of 1883–84 Rs. 1-4-9; thus it will be seen that there was a gradual rise in this respect since 1882–83. The excess in the year under review over its predecessor amounted to 2 annas 6 pies, by which means the income increased from Rs. 17,20,210 to Rs. 19,27,462, and with this increased income the sanitary allotment also was raised from Rs. 5,71,199 to Rs. 6,54,536, the difference in favour being Rs. 83,337. Taken as a whole, the allotment may be considered as adequate; it yields a per-centage of 33·9 to income against 33·2 in 1883–84. Individually considered also the allotments made by each town except five appear to be fair. In Cocanada (19·6), Mangalore (19·5), Calicut (10·4), Vizagapatam (10·0), and Pálghat (8·9), the per-centages are low and below the average. In 1883–84 Ootacamund and Kumbakónam stood first on the list, with proportionately high sanitary allotments. In 1884–85 also they maintained their positions. The per-centages varied from 8·9 in Pálghat to 66·3 in Ootacamund. Next to Ootacamund and Kumbakónam (59·8) come Salem with 55·0, Madura 52·9, Trichinopoly 48·0, Coonoor 44·6, Tinnevelly 43·6, Tuticorin 41·7, and Tanjore 40·1. In 15 towns the per-centages were between 30 and 40, in 18 between 20 and 30, and in the five others they were below 20 down to 8·9 in Pálghat.

Of the total sanitary allotment, Rs. 3,84,751 were spent in the nine months of the year ending December 1884, leaving over Rs. 2,69,785, or something more than one-third, to be spent in the following three months of the year in 1885. Taking the figures for 1883–84, which represent the transactions for the whole year, it is seen that Rs. 5,41,644 out of an allotment of Rs. 5,71,199 were spent, leaving Rs. 29,555 unutilized

Local Fund Circles.

In 1883 the Local Fund Circles in the presidency were 30 in number, accounted for by some districts being divided into two or more circles; but in 1884, by a notification published in the *Fort Saint George* and *District Gazettes*, the districts of North Arcot, Ganjam, Godávari, Kistna, Cuddapah, Tanjore, Madura, Tinnevelly, and Salem, were declared to be Local Fund Circles, *i.e.*, the separate circles which each of them contained were combined and the whole district formed into one circle; thus there are now only as many circles as there are districts, and these are 21 in number excluding Madras. Sanitary reports were received from all of them.

Water-supply, Drainage and Conservancy.—There is nothing particular to note in these respects. The sources of water-supply were the same as those formerly reported upon, viz., tanks, wells, rivers, irrigation channels and canals, and in the generality of instances the quality is favourably reported upon. Greater efforts are being made year by year to conserve some of the principal sources for drinking purposes only, by the employment of watchmen to prevent them from being polluted. Except in a few cusbah towns where some stone drains exist, the drainage is mostly very primitive, consisting of ditches cut in the soil in the sides of the streets and thoroughfares, and house drainage either flows into these, into cesspools, or into the backyards where it soaks into the soil. In last year's report a retrograde movement was noted in conservancy; during 1884 it appears to have fallen still further back. Out of a total of 52,003 villages only 565 were conserved, against 576 in 1883. This backwardness is observable in 6 out of the 21 circles, viz., in Anantapur the number of villages

conserved fell from 13 in 1883 to 7 in 1884, in Chingleput from 17 to 14, in Coimbatore from 79 to 35, in Malabar from 6 to 3, in North Arcot from 28 to 18, and in Tanjore from 39 to 37. Anantapur, Tanjore and Trichinopoly figure in the reports for the past three years also with deficient conservancy year after year. Now that Act V. of 1884 (the Madras Local Boards Act) provides for the prohibition and removal of obstructions and the cleansing of tanks, streams, wells, and unwholesome buildings and lands in all rural areas, it may be expected that greater attention will be paid to village and town sanitation under the powers conferred by it.

Sanitary works.—Details of the sanitary works executed in each circle during the year are given in the abstracts of the sanitary reports. They consisted chiefly in the sinking of wells and excavating tanks, in the erection of latrines and dust-bins, improving and repairing drains, cleansing tanks and wells, removing rank vegetation, improving village sites, &c., and some other minor works. In some circles more was done than in others; in three districts—Malabar, Nellore, and Nilgiris little or nothing seems to have been done. The amount of work executed in any district may be gauged from the amount expended on sanitation. In this way North Arcot, Tanjore and South Arcot stand high on the list. The sanitary expenditure in them amounted to Rs. 20,005, 16,230 and 15,718, respectively.

The aggregate available income (one-third of the land cess) for the year 1884–85 amounted to Rs. 14,02,971, against 13,84,617 for 1883–84, *i.e.*, the districts as a whole were richer by Rs. 18,344 during the year under review than its predecessor. Of this amount, Rs. 3,72,946, or 26·5 per cent., were allotted for sanitation, against Rs. 3,99,672 or 28·8 per cent., in 1883–84, being Rs. 26,726, or 2·3 per cent., less; *i.e.*, the more the available income, the less was the amount appropriated for sanitation. "Improvement of village sites" and "other sanitary objects" suffered chiefly by the reduction, while an improvement is observable in the allotments for the other items over the preceding year. Out of a sanctioned allotment of Rs. 3,72,946 for 1884–85, only Rs. 1,97,457 were expended, leaving Rs. 1,75,489, or a little less than half, to be spent in the concluding three months of the year. From past experience the whole of this amount would probably not be spent, but some money be left unutilized at the end of the year. In the year 1883–84, which represents the transactions for the entire period, we find that out of Rs. 3,99,672 only Rs. 3,08,288 were expended, leaving Rs. 91,384, or little less than one-fourth of the grant, unexpended. Under no one of the items was the sanctioned amount fully utilized. The same thing occurs year after year, and will most probably occur in 1884–85 also, notwithstanding the recent orders of Government and the Board of Revenue, which enjoined the complete utilization of the funds allotted for sanitation.

In some districts larger allotments have been made than in others. Eliminating the Nilgiris for obvious reasons, and Malabar and Canara, the conditions of which are such that no large outlay is devoted to conservancy, the rates varied from 10 per cent. in Coimbatore to 38 per cent. in South Arcot. In 7 districts there were between 25 and 36·7 per cent., and in 9 others between 15·9 and 22·5 per cent. Excepting in Coimbatore 10·0 per cent., Ganjam 15·9, Chingleput 17·3, Madura 18·0, and Godávari 19·2, the sanitary allotments of the other districts may be considered as fairly adequate, the only regret being that they were not always utilized to the full extent.

General Remarks.

As I did not take charge of the office till after the close of 1884, I have nothing to say under this head, but Surgeon-General M. C. Furnell, my predecessor in office, has furnished the following notes for insertion in the report:—

During the early part of the year the northern municipalities, Masulipatam, Guntur, Ellore, Rajahmundry, and Cocanada were visited by the Sanitary Commissioner, and those still further north, Berhampore, Chicacole, Vizianagram, Bimlipatam, Vizagapatam, and Anakápalle by the Deputy Sanitary Commissioner; besides these he also visited the municipalities in the districts of Cuddapah, Salem, Bellary, Anantapur, Kurnool, and Tinnevelley during the year. The difficulty of communication in the northern districts renders visiting them extremely difficult; and in some of the municipal towns and districts public bungalows have been done away with, so that an inspecting officer, ignorant of the fact, may arrive and find that he literally has no where to lay his head. Thus at the port of Masulipatam one is landed after a long and tedious sea passage of some four or five hours, in an open boat, from the steamer, on a hot and shelterless quay, and when one asks where is the public bungalow? is

informed there is none; and hotel? none. The municipal town of Masulipatam is some four or five miles further inland, and it is with the utmost difficulty, and after many hours waiting, one can obtain a common country bullock cart to get there. In Masulipatam town itself there is no bungalow, and one is literally obliged to proceed to the first house in *formâ pauperi* and ask for shelter. Some remedy for this state of things seems demanded; if local authorities cannot keep up public bungalows, the old state of things, when they were kept up by Government, might, with advantage to inspecting officers, be reverted to.

During the hot months cholera raged with great violence in the Tanjore collectorate and Government becoming uneasy repeatedly called attention to the fact; this induced Dr. Furnell to visit the district; his report is appended to the Sanitary Commissioner's Report for 1884.

In the months of November and December, North Arcot, Coimbatore, Trichinopoly and Malabar were visited by the Sanitary Commissioner. During the latter part of December and January and February 1885, Dr. Furnell acted as Surgeon-General during the absence of Surgeon-General Cornish on leave, and was therefore unable to tour.

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER FOR BOMBAY FOR 1884.

(Deputy-Surgeon-General T. G. Hewlett.)

General Population.

Vital Statistics.

On the 1st July 1884 the compilation of the Vital Statistics of the Presidency was for the first time entrusted solely to the Deputy Sanitary Commissioners. Up to this date the village returns had been compiled tálukvár by the mámlatdárs of each zilla, but this system had been found to be inefficient, and Government was pleased to sanction an establishment of compilers for the office of each Deputy Sanitary Commissioner who is thus brought each month into direct communication with every village in his district. Advantage was taken of this opportunity to re-arrange the Deccan and Konkan Registration Districts and to alter their designation, so that for the future the Northern Deccan, Southern Deccan, and Konkan Registration Districts will disappear from the Annual Return. The principle observed in fixing the areas of the new districts was to make them co-terminous with collectorates in which the same language is spoken.

The new arrangement has been found to work admirably as the statistics are now received from the villages with much greater punctuality than formerly. Government has been pleased to impress on Collectors the necessity for the village officers submitting their returns to the Deputy Sanitary Commissioner by a fixed date, and the Kulkarnis and Talátis are liable to a fine if any complaint is made regarding the late submission of the returns when due.

In the Presidency of Bombay, including Sind, during the year 1884 the births of 278,986 males and 255,737 females, or a total of 534,723 children, were recorded, against 261,966 boys and 239,835 girls, or a total of 501,801 children in 1883. The recorded births for 1884 are thus 32,922 in excess of those for the previous year, whilst they exceed the mean of the preceding 10 years ending 1883 by 166,165.

The following table shows the number of births registered in each year from 1874 to 1884, their ratios per 1,000 of population and the proportion of males to females:—

Years.	Number of Births Registered.			Rates per 1,000 of Population.			In every 100 Births there were		For every 100 Male Births the Females were
	Males.	Females.	Children.	Males.	Females.	Children.	Males.	Females.	
1874	174,966	157,842	332,808	10·81	9·75	20·56	52·57	47·43	90·21
1875	178,332	161,937	340,269	11·05	10·01	21·06	52·49	47·51	90·82
1876	181,972	165,512	347,484	11·24	10·21	21·45	52·64	47·36	89·95
1877	164,263	147,399	311,661	10·15	9·11	19·26	52·75	47·25	89·73
1878	128,848	114,405	243,253	7·96	7·07	15·03	52·97	47·03	88·78
1879	151,460	136,410	287,870	9·38	8·41	17·74	52·61	47·39	90·06
1880	196,285	174,588	370,873	12·08	10·82	22·85	52·66	47·34	89·91
1881	239,912	219,745	459,657	14·58	13·35	27·93	52·19	47·81	91·59
1882	255,927	235,419	491,346	15·55	14·31	29·86	52·09	47·91	91·98
1883	261,966	239,835	501,801	15·92	14·58	30·50	52·20	47·80	91·55
Mean for 10 years	193,839	175,219	369,558	11·86	10·75	22·61	52·46	47·54	90·63
1884	278,986	255,737	534,723	16·96	15·54	32·50	52·17	47·83	91·67

It is satisfactory to notice the progressive improvement that, except in the three years of famine, has taken place in the registration of births.

The number of births in 1884 was higher in each of the districts than that recorded in the previous year. The total increase for the Presidency was 9·89 per 1,000 of population above the mean of the preceding 10 years.

It is most disappointing to have to bring again prominently to the notice of Government the extremely defective state of the registration of births in the City of Bombay which, as will be seen from the following statement, has steadily decreased year by year.

In 1880 the births amounted to		16,997 or 26·38 per	1,000 of population.
„ 1881	do.	16,381 or 21·19	do.
„ 1882	do.	15,094 or 19·52	do.
„ 1883	do.	14,932 or 19·31	do.
„ 1884	do.	14,377 or 18·59	do.

Bombay instead of setting an example as the leading municipality, occupies a very low place in the list of towns as regards the registration of births, and it is evident that very many births escape registration. I trust that Government will be pleased to invite the especial attention of the Municipal Commissioner to this fact and urge him to take measures so as to secure a much more correct registration.

The recorded birth-rates among the urban and rural populations of the Presidency were respectively 25·53 and 33·52, against 25·07 and 31·29 in 1883. The birth-rates recorded among the rural population of each collectorate except Ratnágiri, Kánara, Ahmedabad, Karáchi and Hyderabad were higher than the birth-rates registered in the urban circles. The same fact regarding the above collectorates was also observed in 1883.

Out of the 55 towns in the Presidency only 12 had a birth-rate exceeding 40 per 1,000 which may be taken as the lowest rate which can be accepted as even approximately correct, although as I shall presently show there are grounds for believing that the birth-rate is in reality higher than this. It seems as if this important subject was entirely neglected in some of our largest municipalities, and especially at places which are the head-quarter stations of the collectorates. This is inexcusable, and it is lamentable to find that for example in the City of Poona a birth-rate of only 15·88 is recorded. I would earnestly hope that Government may be pleased to invite the especial attention of the authorities in each town to the very defective character of the registration of births and to impress on them the absolute necessity of much greater attention being paid to this most important subject.

In 1884 among the civil population in the Town, Rural and Cantonment circles of the Presidency of Bombay the deaths of 214,376 males and 194,033 females, or a total of 408,409 persons, were recorded. In the previous year 420,198 deaths or 11,789 more than in 1884 were registered. The following statement shows the number of deaths registered in each year since 1874 :—

1874	-	278,652	1878	-	532,951	1882	-	343,418
1875	-	375,718	1879	-	387,542	1883	-	420,198
1876	-	368,260	1880	-	328,673	1884	-	408,409
1877	-	627,708	1881	-	381,450			

Excluding the famine years 1877–78, the recorded deaths in 1883 and 1884 were more numerous than in any of the series.

The computed death-rate per 1,000 of population in 1884 was 24·62, against 25·53 in 1883, and exactly the same as the decennial mean. Omitting Sind, where the mortuary registration is extremely defective, the recorded death-rate in the other parts of the Presidency amounted to 26·12 per 1,000 of the population.

The millesimal ratio of males dying to males living was 25·23, and of females dying to females living 24·39. In 1883 these ratios were respectively 26·02 and 25·02. For every 100 females who died 110·48 deaths among males were registered, but these proportions varied considerably in some of the districts.

The mortality amongst infants under one year and children above one year but under five was, as usual, terribly high, in comparison with other periods of life. In fact, the deaths in children under five years of age formed 45·07 per cent. of the total deaths. The extremely high rate of mortality among children of tender years affords unmistakeable proof of local causes of insanitation throughout the Presidency. The period of greatest immunity was in the ages above 10 and under 15, the rate being 6·37 per 1,000. For those "above 60 and upwards" the mortality was at the rate of 58·63 per 1,000. The per-centage on total deaths amongst infants under one year was 23·79, against 21·35 in 1883. For those above one and under five the per-centage on total deaths was 21·28, against 19·19 in 1883. For old people above 60 and upwards the per-centage on total deaths was 10·66, against 10·38 in 1883.

The subjoined table shows the deaths in 1884, arranged according to the specified causes laid down by the Government of India and contrasted with the results for 1883

and the mean of the preceding 10 years. The causes of deaths will be more particularly noticed in the next section :—

Deaths by Causes.	Mean of 10 Years, 1874-83.		1883.		1884.	
	Number.	Ratio per 1,000 of Population.	Number.	Ratio per 1,000 of Population.	Number.	Ratio per 1,000 of Population.
Cholera	25,888	1·56	37,954	2·31	13,804	0·84
Small-pox	6,869	0·42	13,404	0·81	14,438	0·88
Fevers	263,385	16·16	266,741	16·21	276,989	16·83
Bowel complaints	34,053	2·09	35,292	2·14	35,983	2·19
Injuries	6,443	0·40	5,978	0·36	5,570	0·34
Other causes	68,819	4·19	60,829	3·70	61,625	3·74
All causes	404,457	24·82	420,498	25·53	408,409	24·82

Cholera.

During 1884 cholera caused 13,804 deaths throughout the Presidency, or 24,150 less than in the preceding year. The epidemic was most severely felt in the Southern Registration District, as 8,534 of the total deaths were recorded in it, of which 4,655 took place in the Dhárwár collectorate. Thar and Párkar collectorate alone in the Sind District enjoyed perfect immunity from cholera, all the other collectorates in the Presidency having been affected more or less during the year under report.

The total number of deaths from cholera in each of the 19 years ending with 1884 were as follows :—

1866	28,027	1873	283	1879	6,937
1867	5,143	1874	37	1880	684
1868	6,347	1875	47,555	1881	16,694
1869	52,330	1876	32,117	1882	7,904
1870	2,666	1877	57,253	1883	37,954
1871	5,821	1878	46,743	1884	13,804
1872	15,642				

so that the number of cholera deaths in 1884 was 24,150 less than in 1883, and 11,585 below the decennial mean; and was exceeded in 9 out of the 19 years above quoted.

I have shown the statistics of Sind separately, as its physical condition and therefore its epidemiological history differs from the rest of the Presidency. For example, in 1874, 1877, 1880, and 1881, or four years out of the 10 included in the form, there was no cholera at all in Sind; and in 1875, with the exception of 42 deaths in the Karáchi collectorate and six in Thar and Párkar, the remaining collectorates were free. In 1876 there were 88 deaths in the Thar and Párkar collectorate, but none in the other parts of the province. In 1878 there were 26 deaths in the Thar and Párkar collectorate, whilst the rest of Sind enjoyed complete immunity. In 1879 the disease was present throughout the district, but for the next two years there was no cholera in Sind, and in 1882 only three deaths occurred in Thar and Párkar.

The immunity from cholera which Sind, as a general rule, enjoys, is of deep epidemiological interest, and I attribute it to a great degree to its extremely dry climate and the very light rainfall. It has only appeared in two years of the series in the Karáchi collectorate, 1875 and 1879. In 1875 it appeared in November but died out in December. In 1879 it commenced in May, attained its maximum in June, and died out completely in September. In Hyderabad collectorate, during the 10 years, it was only present in 1879. The disease commenced in May, attained its maximum in June and died out in July. Thar and Párkar collectorate has suffered more severely than the rest of Sind, as the disease was present in five out of the 10 years. In 1875, five deaths were reported in June and one in July. The next year it began in May, continued in June and July, but died out in August. In 1877 there was no cholera, but in 1878 there were seven deaths in March and 19 in April when it ceased. In 1879 there were eight deaths in May and 66 in June, but no more during the year, and since then with the exception of three deaths in May 1882, there was no more cholera in Thar and Párkar. In the Shikárpur collectorate cholera was

only present in one year, 1879, out of the 10 years. It commenced in May, attained its maximum intensity in June, but died out in November. In the Upper Sind Frontier also the disease only appeared in 1879. It commenced in May, attained its maximum in June, and died out in July, since which time it has been free. The disease broke out in the Shikárpur collectorate on the 2nd October 1884; on the 14th it appeared in the Upper Sind Frontier collectorate, on the 15th in the Karáchi collectorate, and on the 19th in the Hyderabad collectorate. Thar and Párkar escaped. In the Upper Sind Frontier collectorate the disease ceased in November, and at the close of the year it had nearly disappeared from Shikárpur and Hyderabad, but still prevailed in the Karáchi collectorate.

In the Presidency out of 13,804 cholera deaths registered during the year 7,448 occurred among males and 6,356 among females; so for every 100 deaths among males there were 85 deaths among females. The ratio per 1,000 of males dying to males living was 0·88, and of females dying to females living 0·80. Last year they were 2·34 and 2·27 respectively. The deaths among females exceeded those among males slightly in the Khándesh, Ahmednagar, Poona, Sholápur, Ratnágiri and Kaládgi collectorates; whilst in the remaining 17 affected zillas the reverse was the case.

Out of 283 Registration circles into which the Presidency is divided for registration purposes (221 rural, 55 town and seven cantonment circles) 157, namely, 124 rural, 31 town, and two cantonment circles were affected with cholera. The total cholera mortality was distributed over 1,450 registration units, *viz.*, 31 towns, two cantonments, and 1,417 villages. Out of the entire population (16,454,414) of the Presidency 4,629,175 persons or 28·13 per cent. were living in the affected localities. Of these 13,804 or 3 per 1,000 died. Out of 24,536 inhabited villages in the Presidency, 1,427 or only 5·78 per cent. were affected with cholera.

As before noticed, during the year, out of the 24,536 villages in the Presidency 1,417 or 5·78 per cent. were affected by cholera. In the Dhárwár collectorate there are 1,231 villages, of which 421 or 33·19 per cent. were affected. In Belgaum out of 1,073 villages 207 or 19·29 per cent. were attacked, whilst in the Kaládgi collectorate there were 160 out of 1,140 villages or 14·03 per cent. affected. In the Karáchi, Broach, Shikárpur, Thána and Kaira collectorates the affected villages were 96, 78, 68, 64 and 57 respectively; whilst in the remaining 14 affected collectorates they were below 50.

Small-pox.

During 1884 the deaths from small-pox of 7,327 males and 7,111 females, or a total of 14,438 persons, were recorded against 13,464 in 1883, and a decennial mean of 6,869. Small-pox prevailed in an epidemic form in three districts. It was most severe in the Southern registration district, where the ratio per 1,000 of population was the very high one, 2·90 against 0·61 in 1883, and a decennial mean of 0·38. In the Central registration district there was a ratio of 0·72 against 0·70 in the previous year and 0·32 the decennial mean, and in the Sind registration district the ratio was 0·43 per 1,000 of population against 0·33 in 1883 and 0·15 the mean of the previous ten years. In the Western registration district and in the Eastern Gujarát registration district there was a decrease during the year, their respective ratios being 0·39 against 1·54 and 0·77 in the former, and 0·19 against 0·56 and 0·38 in the latter.

According to age 25·8 per cent. of the deaths occurred among infants under one year of age, whilst 37·6 per cent. took place among children over 1 (one) and under 12, the remaining 36·6 per cent. being among persons over that age.

In December 1883, 1,033 deaths were registered throughout the Presidency, and in January (1884) the number rose to 1335, and reached its maximum intensity 2,413 in March. The disease then commenced to decline, and the minimum was registered in October; but the setting in of the cold weather, as usual, appears to favour the development of the poison, as the deaths from small-pox rose in December to 309 or 109 above the number recorded in the month of October.

Fevers.

During 1884, 144,596 males and 132,393 females, or a total of 276,989 persons, were reported to have died from fever. The increase therefore for the year under report as compared with 1883 amounted to 10,248 deaths, the mean for the previous 10 years being 263,385.

In all the districts excepting the western fever has caused higher mortality during the year than in 1883. In the Eastern Gujarát registration district the fever death-rate was the high one of 22·72 per 1,000 of population against 20·04 in 1883 and 20·01 during the previous 10 years. In the Central registration district the ratio was 16·46 against 15·69 in 1883 and 15·12, the decennial mean. In the Western registration district the ratio, 16·19, was nearly as high as in the Central registration district, but

it was lower than the previous year, 18·61, though higher than the decennial mean, 15·88. The ratios in the Southern and Sind registration districts were exactly the same, 14·47, during the year, and both were higher than in 1883, but in the Southern registration district it was lower than the decennial mean, 17·89.

The death-rate from fever in the urban zillas of the Presidency amounted to 13·83 per 1,000 of population against 12·44 in the previous year, but among the rural population it amounted to 17·27 against 16·76 in 1883. This fact was pointed out in my report for 1883 as proving the necessity for improving village sanitation.

The highest death-rate from fever is reported to have occurred at Viramgám, a town in the Ahmedabad collectorate, where it attained the enormously high rate of 42·60 per 1,000 of population against a zilla rate of 22·98. In only 14 towns situated in 8 different collectorates, excluding the City of Bombay, the death-rate from fever is higher than the average death-rate of the zilla. In the Sholápur collectorate there are three towns, viz., Sholápur, Bársi and Pandharpur, and in all, the town rate is higher than in the collectorate. In the town of Ratnágiri the death-rate from fever is higher than that of the zilla. In Kaira collectorate, with the exception of Borsad, the town rate is higher than the average death-rate of the zilla. In the Ahmedabad collectorate in the towns of Ahmedabad and Viramgám the rate is much higher than the average district rate. In Hyderabad the rate is higher by 1·72 than the zilla rate. In Umarkot it is nearly double that of the zilla rate. In the two towns of the Shikárpur collectorate, viz., Shikárpur and Lárkhána, the rate is higher than the zilla rate, so also Jacobabad has a higher rate than that of the collectorate. The attention of the municipal authorities is invited to the above fact, and they should lose no time in investigating the local causes of the high mortality from fever within their municipal limits.

Bowel complaints.

During 1884, bowel complaints caused the deaths of 19,953 males and of 16,030 females, or a total of 35,983 persons against 35,292 in 1883 and a decennial mean of 34,053. By districts the Southern registration district headed the list with the very high ratio of 4·20 per 1,000 of population against 3·48 in 1883 and 3·40, the decennial mean. Gujarát comes next with a ratio of 2·71, and next to it is the Western registration district, 2·09, and following it is the Central registration district, 1·84, and the last of all is Sind with a rate of 0·26 per 1,000. In the Presidency the rate was 2·19 against 2·14 in the previous year, and a decennial mean of 2·09. The last three districts show a slight increase in the death ratios, whilst in the first two there was a slight decrease.

Injuries.

During 1884, 3,231 males and 2,339 females, or a total of 5,570 persons, met with violent deaths. The mortality from these causes is less by 408 than in 1883 when 5,978 deaths were recorded. Of the 5,570 deaths 2,461 were caused by drowning, 1,077 resulted from snake-bites, 415 from wounds, 213 by hanging, 121 by poisoning, 118 from attacks by wild beasts, and 1,165 from causes not specified.

Other causes.

The recorded deaths from causes other than those specified numbered 61,625, 31,821 of which occurred among males, and 29,804 among females. The total for 1883 was 60,829, so for this year there is an increase of 796.

Vaccination.

The following table contrasts the work amongst the civil and military population during the year under report with that for 1883–84 :—

Establishment.	Persons primarily vaccinated.				Persons re-vaccinated.				Total Number of Persons operated on.			
	1884-85.	1883-84.	Increase.	Decrease.	1884-85.	1883-84.	Increase.	Decrease.	1884-85.	1883-84.	Increase.	Decrease.
In Civil Life.												
Itinerant	774,511	792,784	—	18,473 2·33	50,990	50,494	9,505 18·82	—	824,310	843,278	—	18,968 2·25
Dispensary	24,014	29,986	—	5,972 19·92	1,780	2,525	—	745 29·50	25,794	32,511	—	6,717 20·66
Total	798,525	822,770	—	24,445 2·97	51,770	53,019	9,505 17·93	745 1·41	850,104	875,789	—	25,685 2·93
In Army Life.												
Native Army	3,554	3,698	—	144 3·89	1,435	2,846	—	1,411 49·58	4,989	6,544	—	1,555 23·76
British Army	328	497	—	169 34·00	147	1,009	—	862 85·43	475	1,506	—	1,031 68·46
Total	3,882	4,195	—	313 7·46	1,582	3,855	—	2,273 58·96	5,464	8,050	—	2,586 32·12
Total for the whole Presidency.	802,207	826,965	—	24,758 2·99	53,361	56,874	9,505 16·71	3,018 5·31	855,568	883,839	—	28,271 3·07

Eight hu[illegible] vaccinated a[illegible] showing a net [illegible] net increase of 6,[illegible] able decrease (68·[illegible] figures being 475 a[illegible] re-vaccinations was 5·31 [illegible] being 85·43 per cent. On the [illegible] words, for every hundred person[illegible] have been 97·93.

Out of 802,207 persons primarily vaccinated [illegible] 95·29 per cent., being 0·40 per cent. below 1883–8[illegible] cases was in excess of that in the preceding year, being [illegible] thousand eight hundred and sixty-eight persons were ope[illegible] account of the failure of the first operation, and in 21,[illegible] unknown. During the year 63,361 persons were re-vaccin[illegible] 1883–84. In 64 instances the re-vaccinations were repeated [illegible] result could not be ascertained, and in 14,406 the operations [illegible] successful cases was 41,255, or 65·11 per cent., against 66·21 [illegible] The total number of persons operated on was 865,568, and of t[illegible] per cent., were successful. In 1883–84 the per-centage was 93·79, [illegible] operated on more than once; the "unsuccessful" numbered 33,014 a[illegible] cases were 29,786.

In primary vaccinations the per-centages are higher than in the [illegible] Government, municipal, and cantonment establishments, and in th[illegible] The highest per-centage is 99·12 in cantonments and the lowest is 87·[illegible] Army. The next highest is 96·63 in Government and the next low[illegible] dispensaries. In re-vaccinations the lowest per-centage is 55·99 in ca[illegible] the highest is 89·68 under Government.

The age details are compiled for three periods, viz., under one year, betw[illegible] six, and above six years. The numbers under each period primarily vacc[illegible] respectively 525,905, 257,938, and 18,364, against 504,282, 298,582, and 24,1[illegible] the preceding year. At the rate of 31 per 1,000 of population, and on t[illegible] population of 25,615,528 there were successfully vaccinated 63·41 per cent., against [illegible] in 1883–84, 59·01 in 1882–83, 58·35 in 1881–82, 49·27 in 1880–81, and 39·78 in 187[illegible] Thus each year is characterised by progress in the protection afforded to infants.

Animal vaccination was carried on in Bombay, Poona city and cantonment, Broach and Kaira collectorates and Jámnagar. The operation of inoculating heifers was generally successful. In Western Gujarát animal vaccination was, before the cold weather tour, carried on in Jámnagar by the Assistant Superintendent of Vaccination, who successfully inoculated nine heifers and distributed the lymph among the vaccinators. Except in Bombay, where animal lymph only is used, and in Poona, Broach, Ankleshvar, Nadiád, Borsad, A'nand and Jámnagar, where both animal and human lymph were in use, vaccination in all other places was carried on from arm to arm and with human lymph. Vaccination with animal lymph was also carried on in Bandora.

Taking together the work of all the Deputy Sanitary Commissioners, Superintendents of Vaccination, Assistant Superintendents of Vaccination, and Inspectors of Sanitation and Vaccination, there were 4,546 encampments, 87,076½ miles travelled in 8,063 days, and 332,759 children inspected in 12,709 villages. Out of every 100 persons operated 38·44 were this year inspected, against 40·76 in the preceding year.

In Bombay the Compulsory Vaccination Act has been in force for seven years, and in Karáchi for five years, and in both places there has been, since the introduction of the Act, a considerable increase in the number of infants protected.

Sanitary Works.

The actual outlay on sanitary works (Military) during 1884 amounted to Rs. 98,885. Military Works.
Of this sum Rs. 34,948 were expended at Ahmedabad, of which Rs. 34,591 were for constructing hospital for British troops. At Deesa Rs. 4,751 were spent, of which Rs. 2,866 were for constructing latrines for Native infantry, and Rs. 1,035 for erecting contagious disease ward to the Native Cavalry Hospital. At Nasirabad Rs. 22,627 were expended, of which Rs. 14,382 were for constructing a new circular storage tank and filter-bed in connexion with the water-supply scheme. At Indore Rs. 2,062 were expended on a new pucca well for the Native infantry lines. At Hyderabad Rs. 6,477 were spent, of which Rs. 5,815 were for improving the drainage of military buildings.

[redacted] the upper
[redacted] from the iron
[redacted] pipes to convey

[redacted] ven in the Sanitary
[redacted] palities during the year
[redacted] conservancy by them was.

[redacted] ceedings and General Remarks.

[redacted] e year I was on tour in the Ahmednagar districts, and
[redacted] ern tálukas of the Poona collectorate on my way to Pand-
[redacted] a, after visiting which I proceeded *viâ* Sángola and Dufflápur
collectorate, where I inspected four municipal towns and
[redacted] hápur and Sátára. In April I went to Ahmedabad to report on
[redacted] ikwár's Haveli for a central jail, and on my return to Bombay
company with the Inspector General of Prisons to select a site
passed May at Mahábleshvar and spent the rains at Poona, but
[redacted] ay in September to meet the English Cholera Commissioners In
[redacted] to Ahmedabad, and with the Inspector General of Prisons selected
[redacted] jail. On my return to Poona I visited Ahmednagar, but received
[redacted] ernment to report on the sanitary condition of the mills and factories
[redacted] hich work I was engaged until nearly the close of the year.

[redacted] ore important events of the year I must notice the appointment of a
[redacted] Officer of the Port, which was sanctioned in Government Resolution,
[redacted] tment, No. 1,979, dated 10th June 1884. The Government of India
[redacted] e officer nominated to the post should belong to the Bombay Medical
[redacted] placed under the orders of the Sanitary Commissioner. Surgeon
[redacted] D., was accordingly appointed and took charge of his duties on the
[redacted] Government was pleased to allow him a clerk, two peons, and to permit
[redacted] to be constructed for his use.

[redacted] o record as likely to exert a most important influence on the sanitary
[redacted] the Presidency the appointment of a consulting sanitary engineer for the
[redacted] of Bombay. As far back as 1876 I had, whilst acting as Sanitary Com-
[redacted] represented to Government the great need of such an officer, and in July I
brought the subject again forward, for as head of the Sanitary Department I was constantly feeling that I was called upon to report on schemes which demanded the knowledge of an expert. Moreover, however tardily, sanitary measures are engaging the attention of municipalities throughout the Presidency, and I am very desirous that, especially as regards structural works of sewerage and drainage, no mistakes should be made, for if they are, discredit will be brought upon the water carriage system and pipe sewers, which would be a great discouragement to those interested in sanitary reform in India.

It is not reasonable to suppose that every district engineer, however able and efficient he may be in his own branch of engineering, is qualified to undertake the design of especial sanitary works. Sanitary engineering is as much a speciality and as distinct a branch of engineering as obstetric or opthalmic surgery are in curative medicine or surgery.

Engineers too in India have hitherto had no opportunity of studying or practising sanitary engineering on a large scale, and consequently are not, as a rule, qualified to deal satisfactorily with the subject. Mistakes which I can only term hideous have been made in past years. I need only refer for example to the arrangements originally designed and carried out for the disposal of nightsoil and bathing water from Government House, Ganesh Khind, to show the necessity of having some officer to refer to who has made sanitary engineering his special study. I accordingly submitted to Government the name of Lieutenant-Colonel Ducat, R.E., as an officer who had specially studied the subject in England and whose report on the drainage of Poona had received the highest commendation from Sir Robert Rawlinson.

Government in sanctioning my proposal was pleased to say that my suggestion was only reasonable and proper, and pointed out that when the Sanitary Commission for Bombay was first formed in 1864 it consisted of a president, three members and a secretary. One of the members was an engineer who in addition to his other duties acted as professional adviser to the president, and on that account received a special allowance of Rs. 300 per mensem.

His Excellency the Governor in Council proposed with the sanction of the Government of India to inform municipalities that Government will be prepared to place at their disposal the services of Lieutenant-Colonel Ducat, an officer specially qualified to advise in such matters on the municipality paying, during the period for which he is employed, his salary with the prescribed contribution on account of his pension and leave allowances and such deputation allowance not exceeding Rs. 10 per day, as Government may see fit to fix.

The Government of India was pleased to sanction the above proposal, and Government in its Resolution, General Department, No. 3,952, dated 30th October, appointed Colonel Ducat Consulting Sanitary Engineer for the Presidency of Bombay.

I have already derived the greatest assistance from Colonel Ducat. Plans for the drainage of the new buildings at Elphinstone College, at the European General Hospital, and in the Marine lines have been submitted to him and he has corrected mistakes in them.

I am also very glad to be able to record that the Municipalities of Ahmedabad and Hyderabad in Scind have applied to Government for his services. The former in connection with water-supply and sewerage, and the latter city, which has a good water-supply, for a sewerage scheme.

I am confident that as time goes on other municipalities will follow this good example. Ahmednagar and Surat require structural works to make them healthy, and I would hope that Government will, under the power reserved to itself in the District Municipal Act, insist on Násik and Pandharpur, which are the two places principally visited by pilgrims in the Bombay Presidency, providing themselves with a pure water-supply and a good sewerage scheme.

The report submitted by the Factory Commission during the year must be noticed as embodying measures which, if sanctioned by the Government of India, cannot fail to exercise a very beneficial effect on the health of the large number of persons employed in the mills, &c., throughout the Presidency, and especially in the city of Bombay.

These measures contemplate improvements being effected in the construction of all new mills which it is recommended should only be permitted to be erected according to a standard plan. They provide means for improving the ventilation and for ensuring the effectual removal of impurities suspended in the air as well as for the maintenance of cleanliness.

The Commission recommended that the age at which children should be employed should be raised from seven (as at present) to nine years, and that children should not work for more than nine hours out of the 24, and that all persons under the age of 14 should be considered children.

Women and children employed in factories should be granted four days holidays in each month, and no child should be employed in a factory unless he or she can produce a certificate signed by a certifying surgeon to the effect that the applicant is of the prescribed age and is physically fit.

In the City of Bombay the most important sanitary measure has been the resolution passed by the corporation to undertake the construction of the Tánsa Reservoir, which, on its completion, will ensure the city from the periodical want of water it now occasionally suffers, and will provide the surest means for the safe introduction of water-closets throughout the town. During the year the nightsoil has been sent out through the main sewer to Love Grove, whence it is pumped into the sea. The harbour at Carnac Bandar, therefore, is no longer defiled by the accumulated nightsoil of Bombay.

I must also mention that owing to the philanthropic exertions of the Roman Catholic bishop a house in Trombay has been obtained which is in process of conversion into a leper asylum, which will be of the greatest service in affording proper shelter for the unfortunate lepers in Bombay.

Credit is due to the Deputy Sanitary Commissioners for the zealous manner in which they have conducted their duties during the year. A very great amount of additional work was imposed on them in connexion with the compilation of vital statistics, and to their careful superintendence the success which has attended the introduction of the new system is very largely owing. At the same time I must cordially acknowledge the valuable assistance afforded by the collector and district officers in each zilla by their bringing whenever required pressure to bear on the village officers so as to ensure the punctual submission of the registers of births and deaths when due.

ABSTRACT OF THE REPORT OF THE CALCUTTA MUNICIPALITY FOR 1884-85.

(*Mr. H. L. Harrison.*)

For a comprehensive view of the town improvements effected in Calcutta during the past few years, the report of 1882–83 should be read which carries the narrative up to the end of that year. In the present report the work done during the year will be briefly stated under each of the eight heads there enumerated, viz. :—

(1.) Water supply, both filtered and unfiltered.
(2.) Sewerage.
(3.) Improvement of privies and latrines.
(4.) Structural improvement of bustees.
(5.) Obliteration of tanks and wells and provision of water in lieu thereof by means of bathing platforms.
(6.) Surface conservancy and surface drainage of bustees.
(7.) Measures for improving cowsheds and cattlesheds in the town.
(8.) Structural improvements in the streets of the town.

Water supply.

(1.) *Filtered supply.*—In the report for 1882–83 the figures were given showing that by better attention to filters, and by economising in every way, the daily supply of filtered water had risen from 6,500,000 gallons daily, originally provided, to 7,400,000 gallons, and then to 7,825,000 gallons daily throughout 1882, and to 8,050,000 in the first quarter of 1883. This supply has since been fully kept up. During the three hot months of 1883–84 an average of 8,278,000 gallons was conveyed into the town, and taking the 12 months as a whole, the daily average amounted to 7,976,000 gallons; in 1884–85 the supply for the three hottest months was 8,317,415, and for the whole 12 months 8,207,330.

The most important extension work is the new 48-inch main, which has to be laid between Pultah and Tallah. A contract for this was entered into with Messrs. Cochrane Grove and Co. on the 2nd October 1883 and towards the end of the rains of 1884 the pipes began to arrive. No time was lost in commencing to lay them as soon as the cessation of the rains made the ground favourable for such operations. The services of two skilled pipe-layers were obtained from England, and by the end of April 2,255 out of 5,720 pipes (the total number to be laid) had been laid, and by the end of June the number had increased to 3,249.

Due steps have been taken to push on with the subsidiary works. The necessary land has been acquired at Pultah for the new filters and settling tanks. The additional engines and machinery requisite for the Tallah and Wellington Square pumping stations have been ordered from Messrs. James Watts and Co., and tenders obtained for the new engines at Pultah. Besides this, the Commissioners have decided on erecting a new pumping station for the west of the town on certain land belonging partly to them and partly to Government in Halliday Street, and have obtained Government sanction to the project. They are, however, very much hampered in pushing on with the works by the want of funds. The Calcutta money market has been most unfavourable. The Government of India in April 1884 advanced the Corporation five lacs, and has allowed the loan to be retained without interest up to the 31st July next, and in October, when the Calcutta market was for a few weeks more easy, the Commissioners succeeded in obtaining 15 lacs at 5 per cent.; but soon afterwards money again became scarce to an almost unprecedented extent, and the obtaining a further loan was out of the question. In the face of these difficulties the Commissioners, who had already entered into contract for the 48-inch main and the Tallah machinery, did not feel justified in assuming any fresh responsibilities until they saw their way to obtaining the funds necessary to meet them. They have therefore advertised a loan for 25 lacs in July, and are waiting the result before entering into further contracts. An application to Government to finance them temporarily in the

event of their pushing on with the works, and not being able to obtain the money in the local market, has not been acceded to.

Extension of unfiltered water supply.—The new pumping station at Mullick's Ghat was completed before the beginning of the year under report, but it could not be used because the attempt to sink a well in the river bank, and thus connect the suction-pipe with the river, proved a failure. A jetty had therefore to be constructed, and after much delay the station began working on the 28th February. It soon appeared, however, that its pumping power could not be adequately utilised until the pipe system had been enlarged. The engines could pump 400,000 gallons an hour, but the pipes at a safe pressure could not carry more than 250,000; and it is precisely in the conveyance of a full supply during certain hours of the day, when unfiltered water is simultaneously needed for road watering, latrines and night-soil depôts and bathing platforms, that the advantage of the more powerful engines would be most appreciated. Larger pipes had therefore to be substituted, and the work of changing them was still going on at the close of the year.

(2.) *Sewerage.*—The sewerage of the town, with the exception of Hastings and Baug Bazar, has nearly been completed; operations are now limited to supplementary work designed to complete the system where it was left imperfect. The expenditure during the year was 1,20,698. The Hastings project was at last carried at a meeting of the Commissioners held on the 7th February 1885; the opposition of the inhabitants having been overcome, it has been taken in hand during the present year. The Baug Bazar project is partly approved of, but the engineer is still unable to see his way to overcoming certain difficulties. The survey of the suburban area lying between Circular Road and the Canal has been completed, and a scheme is under preparation which will necessitate the sanction of Government under section 168 of the Act. Drainage.

(3.) *Improvement of Privies, Latrines, &c.*—As regards the reconstruction of privies, the progress made during the year was very good, though not equal to the high-pressure rate of the two preceding years. The figures are—new privies sanctioned according to improved plan:—

Year.	No.	Year.	No.
1878 - - -	744	1882–83, 15 months - -	2,836
1879 - - -	435	1883–84 - - -	2,271
1880 - - -	890	1884–85 - - -	1,786
1881 - - -	1,333		

The attention of the Health Department has been specially directed to surface drainage during the year, so as to carry off washings, and the amount of work done in this direction has been much above the average.

(4.) *Structural Improvement and Subsoil Drainage of Bustees.*—So far as the expenditure is a guide, this work has been pushed on during the year with considerable energy. There was no relaxation of effort, and the impetus given to the work in 1882–83 was fully sustained.

(5.) *Obliteration of Foul Tanks and Wells, and substitution of Bathing Platforms.*— Tank-filling has been pressed on with energy during the year, and 29 tanks have been filled up by the Corporation in addition to four filled up by the owners during the year. A new policy has been formally adopted during the year, viz., wherever possible, to purchase the tank, and either convert it into a square, or utilise it for cowsheds, bathing platforms, or washing reservoirs. The site of a filled-up tank in Komedan Bagan has been converted into a square, the adjacent portion not needed for the square being sold. A tank at Tollolah belonging to Maharajah Sir Joteendro Mohun Tagore, K.C.S.I., which was filled up by the Corporation, has been given up by him to the Corporation to form into a square, on condition of further land being acquired to enlarge it, and the square being called after his father. The ground covered by two tanks filled up in Jorapukur bustee has been acquired for construction of model cowsheds and washing reservoirs. Other similar projects are under consideration. Tank filling.

The usual opposition which tank filling with refuse evokes culminated in a prosecution for thus filling up a tank in Komedan Bagan in the proximity of the new square. In the present instance the case was energetically defended, and medical evidence in favour of the practice cited, and the magistrate, after visiting the site, dismissed the complaint.

Wells.

Although the law gives the Corporation no power to close wells, yet all that was possible was done during the year to fill up as many of the most insanitary wells as could be filled up. The Health Officer prepared a list of the worst and most dangerous wells in the town, and 68 were closed by his Department during the year. It will be seen that he expresses a hope that, when the filtered supply is extended, the law may be changed, so as to allow the closure of all the wells in the town.

Bathing platforms.

It was mentioned in last year's report that the construction of bathing platforms had been sanctioned; these had been completed before the close of the year, and the construction of 17 more was only delayed by the difficulty in obtaining the land. The work has been pushed on steadily during the year, and by the end of it 28 were in working order. It admits of no dispute that they have proved a very great boon to the lower classes, even though the water they distribute is only unfiltered water, and numerous applications are now received for their construction in all parts of the town. The water during certain hours of the day is taken off faster than it can be supplied through a large tap, and the reservoir is in consequence all but empty. The multiplication of bathing platforms is somewhat retarded by the insufficient size of the unfiltered distribution pipes already referred to. The consumption of water takes off the pressure from the road watering, and it is necessary to await the enlargement of the pipes before constructing more platforms. Good progress is, however, being made with this; and meanwhile the Bustee Committee have sanctioned the erection of 25 more, two on sites belonging to the Corporation and 23 on sites to be acquired, and it is intended to raise the number in working to 60 by the end of the current year. Besides the large reservoirs for bathing in the newer designs, two smaller reservoirs are attached for washing clothes and cooking utensils. Separate platforms are also constructed for males and females.

Conservancy.

(6.) *Surface Conservancy of Bustees.*—It was reported last year that the Commissioners had sanctioned a special conservancy establishment for the purpose of cleaning bustees and keeping the surface drains in order. This consisted of—

	Rs.
2 Inspectors on	120 to 180
2 Sircars on	14
12 Peons on	7
200 Dhangurs on	5-8
and 32 hired carts,	

and it was computed that out of 207 bustees, with an area of 2,222 bigahs, 72 of the largest, with an area of 1,270 bigahs, had been taken up, cleaned and placed under routine arrangements by the end of 1883–84. During the year under report, the remaining areas have been similarly dealt with, and the whole is now under permanent arrangement. It has been found necessary, however, to increase the staff to 18 peons, 300 dhangurs, and 75 hired carts, which, by the amalgamation of the Bustee and Nuisance Departments effected in December last, are now placed under four inspectors, who divide the town into four portions, each looking after the nuisance and bustee conservancy of his section.

At first only Rs. 80,000 were sanctioned as the Bustee grant for 1884–85, under the impression that, as only Rs. 55,000 had been spent in 1883–84, more would not be needed in 1884–85. It soon, however, became apparent that this was an error; the reason why so little had been spent in 1883–84 was because so much of the expenditure which had really been incurred had not been brought to account before the 31st March, and would therefore swell the expenditure in 1884–85. A further sum of Rs. 53,140, equal to the estimated amount thus anticipated, was added to the grant, and, later on, a further grant of Rs. 10,000 was made. This raised the total grant for the year to Rs. 1,43,140. The expenditure, however, even exceeded this amount, as shown below:—

	Rs.
Establishment and hiring of conservancy carts	45,301
Tank filling	8,536
Land acquisition for improvements	58,799
Road-making and sewering	13,971
Construction of bathing platforms	18,455
Construction of model cattle sheds	11,226
Compensation to hut-owners who were disturbed	1,867
	1,58,254

(7.) *Improvement of Cowsheds and Cattle-Sheds.*—This Department has been under the special superintendence of the Health Officer, who has done all in his power to improve these sheds, but as long as the Commissioners have to proceed against the tenants-at-will, instead of against the owners, the work must be unsatisfactory. According to the Health Officer's Census there are 550 cowsheds in the town bustees, and a very large number of cattle-sheds for draught cattle. Of the former more than half have been connected with the sewer, while 88 have been improved *qua*-drainage and flowing. This has not been effected, however, without painfully-frequent prosecutions, amounting to 1,760 in number.

A commencement was also made during the year in the construction of two model cattle-sheds on land belonging to the Corporation at Kalabagan and Jorabagan. The Engineer undertook the task of erection, and they were substantially though expensively constructed with a lower floor as the stables, and an upper floor for the cartmen to live in.

(8.) *Structural Improvements in the Streets of the Town.*—The proposals of the Sanitary and Structural Improvement Committee for the improvement of the large thoroughfares of the town have already been detailed, and the work done in the improvement of bustees, especially of Jorabagan, has also been related in detail; but, besides this, the Commissioners set aside a sum of Rs. 30,000 annually out of revenue for minor street improvements, and against this grant Rs. 33,848 were actually expended in 1884-85.

ABSTRACT OF REPORT OF THE HEALTH OFFICER FOR CALCUTTA FOR 1884-85.

(Dr. J. O'Brien.)

The returns and report have been prepared for the calendar instead of for the official year, as in the two past years. This change was recommended by the Army Sanitary Commission in their Memorandum on the sanitary report of the town for 1882–83, and approved of by the Town Council at their meeting held on 17th January last. There can be no doubt that the return to the calendar year, as far as the sanitary reports are concerned, is in a high degree desirable. Continuity of record will be thus preserved, and the returns will be far more useful for reference and comparison with the sanitary records of other towns and countries of the civilized world, all of which adopt the calendar year as the period for report.

The meteorology of 1884 was characterized by great drought and excessive heat in the early part of the year. In the preceding year the rainfall was short of the average by 17 inches, and from 1st January to 15th April 1884 the entire rainfall was less than half an inch. The barometric pressure, as shown by the monthly means, was somewhat below the average of the previous year. The months of comparatively lowest pressure were January and July. The temperature of the first two months was considerably below the average, but in March there was a rapid rise [illegible] mean of the month was 0·6° in excess of the average. The heat in April, in the early part of the month, was extreme, and a temperature of 103·7° tered about the 15th, a higher temperature than has been recorded for For the rest of the year the temperature was singularly low. In August below the average, in November 5°, and in December 3·1°. In the early year the humidity was also less than the average.

The rainfall was somewhat below the average, viz., 62·61 inches, against average of the preceding 48 years. The rainfall was chiefly confined to the from May to September. During the first four months hardly any rain fell. 1st January to 30th April the amount collected was 1·75 inches, against 5· average of previous years. The largest fall was in September, viz., 16·63 i against an average of 10·18 inches. In November and December there was practi no rain.

The price of food, though not excessive, was higher than in the preceding year. T dearness of food was the result of the scanty rainfall of the previous year. Scarcity of food was experienced in some of the districts of Bengal; but, beyond a slight rise in prices, there was no distress in the town. Meat and other articles of food in the Municipal Market sold at prices higher than usual in the early part of the year, owing to the influx of people into the town at the time of the Exhibition; but towards the end of the year prices were more moderate.

The registration of births during the year was satisfactory, and shows results better than those of any year of which there is record. Since 1880 there has been a sustained improvement in the registration of births. For the six years prior to 1880 the registered births yielded an average annual ratio of 15·3 per 1,000 of population; but in the four years from 1880 to 1883 inclusive, the average annual ratio rose to 17·2. In the year under review there was a still further increase, and the registered births amounted to 19·1 per 1,000 of population; 8,290 births were registered, against 6,985, the mean of the preceding decade. Former Health Officers have commented on the difficulty of even estimating accurately the real birth-rate of a town like Calcutta, where there is such an abnormal disproportion between the sexes, and where such a large proportion of the population is non-resident. According to the last Census the

population of Calcutta, including the Fort and the Port, consists of 433,219 souls. Of this number 288,817 are males and 144,402 females; that is, there are almost exactly two males to every female.

The birth-rate in England in the 10 years from 1872 to 1881 was 34·4 per 1,000 of population; but this is among a population in which females are slightly in excess of males, the proportion being about 105 females to every 100 males. If we exclude the infructuous surplus of males from the Calcutta population, and calculate the birth-rate in the past year on the female population of 144,402, with the English proportion of males added, viz., about 140,000, we should get a birth-rate of 29·1 per 1,000, or 6·2 short of the English rate. This is a fair rate no doubt, and a considerable advance on any that registration has hitherto afforded in this city. Still, when we consider the large proportion of married women (61·4 per cent.) in the female population at the child-bearing age, that is, between 20 and 40, we are forced to the conclusion that the figures are still short of the truth. In the Census report for 1881 Mr. Beverley goes fully into this question, and, making due allowance for the disproportion of the sexes, estimates that the real birth-rate in the town is about 24 per 1,000 of the ascertained total population. The rough calculation that I give above supports this opinion, and shows that birth registration, though improving steadily, is still imperfect.

During the year several children were vaccinated whose parents could not produce the statutory forms with regard to vaccination which they should have received from the registrars when the births were registered, and it was ascertained certainly in some cases that the births were not registered. All instances of this kind were brought to the notice of the police, with the result doubtless of improving registration. It will be seen on reference to the table that the largest number of births was registered in the last quarter of the year:—

Statement of Births registered from 1874 *to* 1884.

Years.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.	Birth per 1,000 of population, Census of 1881.

1883	642	592	618	516	561	503	543	622	643	723	776	696	7,434	17·1
Mean of ten years	551	502	543	454	509	492	547	589	630	685	700	665	6,985	16·1
1884	705	630	738	676	598	543	607	716	617	837	825	798	8,290	19·1

The death-rate of 1884 corresponds very closely with the decennial average, viz., 30·5 per 1,000 of population, against 30·4, and this notwithstanding the fact that an epidemic invasion of cholera, unprecedented in severity for the past 14 years, occurred in the months of March, April and May, causing 1,616 deaths, against a mean figure for the same months for the 14 years of 605. Small-pox also prevailed to an unusual extent in the months from February to June, and swelled the total of the year by 478 deaths. But the high death-rate of the first two quarters, due so largely to the prevalence of these particular diseases, was counterbalanced to a great extent by the unusually low mortality of the third and fourth quarters, and by the saving of life throughout the year under the head of fevers and bowel complaints as compared with other years. The general climatic conditions which fostered the virulence and intensity of cholera tended to diminish the prevalence of other classes of disease, especially of fevers. The higher rate of mortality was confined to the first two quarters of the year. The total number of deaths registered during this period was 7,301. In the two later quarters the number fell to 5,955. The figures of the first period exceed the decennial mean by 915, while those of the second fall short of it by 848.

Statement of Deaths from the most prevalent diseases from 1874 to 1884.

Years.	Cholera.	Diarrhœa and Dysentery.	Fevers.	Small-pox.	Other Causes.	Total.	Ratio per 1,000 of Population, Census of 1881.
1874	1,245	1,358	4,461	120	4,343	11,527	26·6
1875	1,674	1,579	5,428	720	4,785	14,086	32·5
1876	1,851	1,864	4,361	71	4,817	12,964	29·9
1877	1,418	1,683	5,151	67	5,385	13,704	31·6
1878	1,238	2,010	6,086	1,495	5,467	16,396	37·8
1879	1,186	1,526	4,796	772	4,774	13,044	30·1
1880	805	1,267	3,797	114	5,698	11,681	26·9
1881	1,693	1,491	3,765	133	5,948	13,030	30·
1882	2,240	1,454	3,618	17	5,848	13,177	30·4
1883	2,037	1,307	3,442	73	5,466	12,325	28·4
Mean numbers	1,549	1,553	4,480	358	5,253	13,193	30·4
1884	2,272	1,209	3,618	478	5,679	13,256	30·5

Compared with the other years of the decade, three years, viz., 1875, 1877 and 1878, show worse results, the remaining seven better.

As regards the mortality according to locality, of the 18 wards into which the town is divided, the three southerly wards, skirting the open maidan, viz., Park Street, Waterloo Street, and Fenwick Bazar, which constitute the European quarter, continue to stand *longo intervallo* at the head of the list as the most healthy. The eastern ward of Puddopooker and the northern riparian ward of Coomertolly maintain their places of 4th and 5th in inverted order, with a death-rate close to the decennial averages. In Bamun bustee and Collingah there is an ascent from 13th and 17th places in the decennial order to 6th and 8th in the annual, the death-rate in the former having descended from 34·2 to 29·5, and in the latter from 38·5 to 31·1. The improved death-rate of these wards exhibits in a very remarkable degree the beneficial effects of the extensive sanitary improvements which have been carried out in them recently. There are several large bustees in each which have undergone extensive structural and general sanitary improvements at the hands of the corporation. Foul ponds have been filled up, and bathing platforms supplying purer river water constructed to replace them. Roads have been made through areas previously covered with densely crowded huts, opening space for ventilation and for scavenging operations. Foul open drains have been filled up and obliterated, sewers laid and houses and house premises connected with them. Hydrants supplying pure drinking water have been introduced. Marshy low-lying places have been raised and drained, and house refuse and surface filth of all kinds have been removed by a regular daily service. In fact, places that were once abominably filthy and ill-kept are now clean and regularly attended to. No weightier evidence of the value of the work that has been done can be produced than the saving of life, which is evidenced by the figures upon which I am now commenting.

The unhealthiest wards during the year were Jorasanko and Hastings, with death-rates of 39·7 and 44·6 per 1,000. These wards were also heavily visited by cholera, the mortality from this disease being respectively 5·4 and 6·8 per 1,000. Jorasanko also suffered more from small-pox than any other ward, the ratio of deaths from this disease alone being 2·9 per 1,000 of population. Hastings, as in other years, maintains its unenviable reputation as the worst ward in the town, and this cannot be a matter for surprise when we consider its condition. The native portion of the ward generally known as Coolie bazar is practically a large and crowded bustee. Surface drainge is most defective, and during the whole of the dry season, lasting from October until June, a large amount of the sewage from houses has no means of escape save by soaking into the ground. The system of underground sewers has not yet been introduced into this ward, and the supply of drinking water is inadequate. The water of Tolly's nullah, a turbid tidal creek much polluted by surface tidal drainage and fœcal matter from several thickly inhabited bustees on either side, and by the crews of the numerous boats plying on its water, is largely used for various domestic purposes, bathing, washing, cooking, and sometimes for drinking. The population of the ward is mainly made up of coolies and lascars, men of the poorest circumstances, who dwell there with their families in miserable ill-drained huts. The proportion of children is larger than in any other part of the town, and they form a class eminently susceptible

to the fatal influences of zymotic disease. A large number of cattle, in addition to those kept by Government, are also stabled in the ward in crowded badly-drained byres and stables, and contribute largely to the uncleanliness of the surface; under such circumstances a high death-rate might naturally be expected. The sanitary state of this ward will, however, soon undergo a complete reformation. The project for draining it thoroughly is now under consideration by the Engineer of the Corporation, and it is expected that it will be sewered completely and connected with the general drainage scheme of the city by the end of the year. Moreover, by the end of 1886, when the additional supply of filtered water is brought into the town, there will be an ample supply of pure drinking water, and thus the two most fertile sources of disease will be removed.

The proportion of deaths, exclusive of still-births, at each age and the proportion of persons living at these ages is as follows:—

—	1884. Per cent. of Population.	Total Deaths.	Per cent. of total Deaths.
Under 1 year	1·4	2,663	21·0
1 to 4	5·0	1,126	8·8
5 to 19	20·4	1,337	10·5
20 to 39	48·3	3,599	28·3
40 to 59	20·2	2,171	17·1
60 and upwards	4·7	1,799	14·1

This statement brings clearly into view the proportion of mortality at different life periods. Though infants under one year constitute but 1·4 per cent. of the population, the deaths among them make up 21 per cent. of the total mortality. The terribly high death-rate of infants is one of the largest and gloomiest items in the bills of mortality of the town. Children between the ages of 1 and 4 form 5 per cent. of the population, and their deaths 8·8 per cent. of the mortality. In the next period, viz., between the ages of 5 and 19, the mortality is lowest. Growing persons at these ages form a fifth of the population, and their deaths only a little over a tenth of the mortality. In the next two periods deaths gain on population, and from 60 and upwards the proportion is 14·1 of deaths to 4·7 per cent. of population.

In the following table the mortality of the town is shown in contrast with that of the suburbs for a period of seven years:—

Years.	Town.		Suburbs.	
	Actual number of deaths.	Ratio per 1,000 of population.	Actual number of deaths.	Ratio per 1,000 of population.
1877	13,704	34·6	14,025	55·7
1878	16,396	37·8	17,459	69·4
1879	13,044	30·1	13,835	55
1880	11,681	26·9	11,216	44·6
1881	13,030	30	11,143	44·3
1882	13,177	30·4	10,470	41·6
1883	12,325	28·4	10,429	41·4
Mean	13,336	30·7	12,653	50·3
1884	13,256	30·5	11,389	45·2

For the four years from 1880 onwards there has been a tendency towards an improvement of the suburban figures as compared with those of the town, but in the year under review, which was decidedly an unhealthy year, the order is reversed, and there is a marked rise in suburban mortality without a corresponding increase in the town. The suburban death-rate in 1884 was 45·2 per 1,000, a rate below the average of the septennial period, but considerably in excess of that of the four immediately preceding years. During the three first years of the septennial period the mortality in the suburbs was extremely great, and the annual deaths reached the high figure of 60·0 per 1,000 of population, but in the four succeeding years the rate fell to an annual average of 42·9 per 1,000.

Suburban Deaths in 1884.

Months.	Cholera.	Small-pox.	Fevers.	Bowel complaints.	Other causes.	Total.
January	52	15	373	184	333	977
February	170	57	284	116	250	877
March	465	45	258	98	211	1,077
April	811	47	340	104	266	1,568
May	301	34	263	83	224	905
June	153	23	226	76	196	674
July	66	11	305	119	293	794
August	41	5	289	122	275	732
September	38	3	305	110	275	731
October	50	2	318	145	294	808
November	127	4	491	180	326	1,128
December	127	4	445	253	289	1,118
Total	2,421	249	3,897	1,590	3,232	11,389
Ratio per 1,000 of population	9·6	·99	15·4	6·3	12·8	45·2

During the past year the high death-rate in the suburbs was largely due to an increase in the mortality from cholera. For the five years since 1880, which was a mild cholera year, the deaths from this disease in the suburbs, in common with those of the town, have advanced in an ascending scale, with one slight intermission in 1883, until they reach their highest point in 1884.

For these years the deaths in town and suburbs were as follows:—

	Cholera deaths.	
	Town.	Suburbs.
1880	805	980
1881	1,693	1,879
1882	2,240	2,349
1883	2,087	2,132
1884	2,272	2,421

The question of the relative intensity of cholera in Calcutta and the neighbourhood is discussed more fully in a subsequent paragraph. Here I may briefly say that the amount of the disease in the suburbs is practically almost double that of the town, for, with a population in the proportion of 62 persons to every 100 in the town, the cholera deaths last year were at the rate of 106 in the suburbs to 100 in the town.

In the above table the deaths in the suburbs from the principal diseases are shown. The mortality was as follows:—Cholera 9·6, fevers 15·4, bowel complaints 6·3 per 1,000 of population against 5·2, 8·8 and 2·7, the rates of the same diseases in the town. From this it will be seen that fevers and bowel complaints as well as cholera prevailed with far greater severity in the suburbs than in the town; on the other hand, the casualties from small-pox were less, viz., 0·99 against 1·1 in the town.

In the succeeding paras. the mortality from particular diseases is discussed. Though the mortuary statistics may be accepted as almost absolutely correct as far as the total mortality is concerned, the information which they afford as to the number of deaths from particular diseases can only be regarded as an approximation to the truth. Probably not one-fourth of the persons who died during the year were attended by properly qualified medical practitioners, and as medical certificates as to the cause of death are not compulsory, they were produced in but a very small number of cases. However, it would be safe to say that the statistics are improving in this respect from year to year, and that as the value of mortuary registration is more generally appreciated, a high standard of accuracy will gradually be attained. The cholera figures are doubtless the closest to the truth. Cholera is the one disease above all others in which from the sudden nature of the invasion, the striking symptoms during the attack and the rapid termination in death, fewest mistakes are likely to be committed. Small-pox also would seem to be a sufficiently striking malady to admit of few errors in diagnosis by even an ignorant observer, but during the year several cases of reputed small-pox were reported which, on examination by the officers of the Vaccine Department, turned out to be chicken-pox or measles. Under the general classification of fevers it is probable that many deaths due to pneumonia and other internal inflammatory disorders are registered.

The year has been a favourable one as regards fevers. The deaths registered under this head amounted to 3,618, or 27 per cent. of the total mortality. The total is less than that of eight years of the preceding decennium and 862 less than the average of the decennium. 1883 is the only year in which the fever mortality was less; in 1882 it was exactly equal. Since 1879 there has been a very remarkable and sustained reduction in the fever mortality of the city. During the years from 1874 to 1879 the average annual number of deaths was 5,030, in the four succeeding years, 1880 to 1883, the average fell to 3,655, or nearly 1,400 less, and in the past year the total was 3,618. The diminution in mortality from diseases of this class would appear to keep pace with the extension of the system of underground sewers and with the improved surface drainage and reduced soil moisture which follows the introduction of sewers into undrained localities. Foul cesspools and open drains which are little better than chains of cesspools become obliterated, and house sewage and surface water is rapidly and inoffensively removed, instead of remaining to stagnate and putrefy on the surface. With regard to the local prevalence of fevers, Hastings stands at the head of the list with a mortality of 15·5 per 1,000, against 8·9, the rate of the entire town. The system of underground drainage has not yet been introduced into this ward. Liquid sewage is collected into numerous reservoirs large and small, and removed by means of carts. The method works badly, and sewage constantly stagnates in the drains, escapes from the reservoirs and pollutes the soil. Accordingly, we find that the fever mortality of this small ward maintains a high level from year to year. For the past five years the death-rate was as follows compared with that of the rest of the town:— Fevers.

	Hastings.	Town in general.
1880	18·6	8·8
1881	20·1	8·6
1882	13·7	8·3
1883	19·1	7·8
1884	15·5	8·3

It is satisfactory to be able to report that the necessary funds have been allotted in the Budget of the current year for the thorough drainage of this ward. With an efficient system of well flushed underground sewers, and an increase in the supply of pure drinking water, it ought to become a very healthy ward.

There was no unusual prevalence of any particular form of fever during the year. Enteric fever, as in former years, was conspicuous by its absence. Only nine deaths from this disease were registered. Of these five occurred among Non-Asiatics.

In the following table the deaths from cholera, month by month, for the past 20 years are shown. 1884 completes the twentieth year. Cholera.

Years.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.	Ratio per 1,000 of population, Census of 1861.
1865	136	396	508	756	400	131	162	394	496	482	317	452	5,978	11·7

Suburban, 1884	72	170	465	811	361	153	66	41	38	50	127	127	2,421	9·6

Reviewing this epoch according to the quinquenniums into which we find it almost naturally divided by the variations of the intensity of cholera, we have first what might be called the pre-sanitary period—the period prior to the great sanitary event of the introduction of a pure water supply—extending from 1865 to 1869. During this period cholera maintained what may be termed a maximum rate. The total deaths were 21,942, and the yearly average 4,388. Next follows a period of minimum prevalence, the lowest figures being found in 1871, the lowest for the whole 20 years. The total deaths in these five years were 5,806, and the yearly average 1,161. In the two succeeding periods we find gradually rising figures, marked by an intermission in the years 1879–80. In the first of these later periods, viz., from 1875 to 1879, the total deaths were 7,467, and the yearly average 1,493, while in the last quinquennial period the total rose to 9,407, and the yearly average to 1,809. Thus then, though the general prevalence of cholera is vastly diminished as compared with the period antecedent to 1870, we find that there is a tendency towards exaltation in the mortality from the disease during the past 10 years. How is this increase to be explained? *Primâ facie* it would appear reasonable to conclude that the health conditions of the town have disimproved of late, and that the increased cholera is due to an increase of filth and to growing defects of conservancy. But so far from this being the case, we have convincing evidence that it is not so in the report of the Commission appointed by Government last year under Section 28 of Act IV. of 1876, to inquire into the sanitary state of the town. The Commission submitted its report in January of the present year (1885). The following extracts from the report refer to some of the sanitary improvements that have been carried out in the town within the last eight years:—

Para. 8.—Acknowledgment of work done * * * * * *

"Our inspections have satisfied us that real and solid progress has been made in the path of sanitary improvement, and it is, as we conceive, our duty to report this fact to the head of the Government from whom we derive our Commission. One of our body, Mr. Beverley, can speak from personal experience on this matter. In 1876, shortly before the present municipal constitution came into being, Mr. Beverley was charged with the duty of taking a census of the town, and in the course of those operations there was almost no part of the town that he did not visit; in 1880, again, he acted as Chairman of the Corporation for upwards of seven months; and in the following year he was again employed to take a census of the town. Mr. Beverley is thus in a position to compare the state of the town at the present day with what it was eight and four years ago respectively, and it gives him great pleasure to be able to place on record his personal testimony as to the great improvements that have been made, more especially within the latter period. That these improvements have benefited the town from a sanitary point of view cannot, we think, admit of doubt, though the fact may not be capable of easy demonstration from the mortuary returns.

"According to the last Annual Report (1883–84) the mileage of sewers completed appears to be as follows:—

	Miles.
First and second class (brick) sewers -	36·77
Third class (pipe) sewers - -	127·79
Total	164·56

"It would seem, therefore, that during the last seven years something like 80 miles of sewers have been laid, or nearly half the total mileage. It is true that the sewers laid during that period have been almost exclusively pipe sewers, the labour and cost of laying which is not to be compared with that of constructing the first and second class (brick) sewers. On the other hand, it is the laying of these pipe sewers that completes and gives its utility to the entire system. It is the branch sewers that collect the material for the principal sewers by providing facilities for drainage all over the town. They not only carry off house sewage and kitchen slops that would otherwise sink into and pollute the soil, but they also drain off rain-water, and so tend to keep the surface of the ground dry and wholesome. In other words, they take the place of the old open public ditches, which have to a great extent been obliterated. It would appear that during the last eight years over 31 miles of these ditches have been sewered, and we are informed that not more than four or five miles of them now remain to be dealt with.

"Till within the last four years little or nothing had been done to improve the bustees of the town. . . . The first bustees taken up under Sections 280 and 284 were Seortee Bagan and Patwar Bagan, and since then several other bustees in the town have been dealt with under these Sections. In order to show the sort of work that is being effected in this direction, the following table has been compiled from information supplied in the annual report for 1883–84 for those bustees in which the operations have been completed :—

Name of Bustee.	Area of Bustee in Bighas.	Length of new Bustee Roads made.	Area of such Roads.	Length of Surface Drains.	Length of Sewers laid.	Amount referred by the Corporation.
		L. ft.	S. ft.	L. ft.	L. ft.	
Seortee Bagan - -	64	5,080	50,375	4,655	2,055	28,768
Patwar Bagan - -	40	1,695	13,055	1,885	—	728
Jorapooker and Gowalapara -	9	1,397	12,573	1,397	—	Not given.
Baman Bagan - -	25	1,380	15,590	1,380	—	Do.
Kola Bagan - -	60	5,000	53,340	4,040	1,800	Do.
Total - -	198	14,552	145,033	13,357	3,855	—

"The roads made through these bustees are generally of a width of 9 feet, sufficient to admit conservancy carts for surface-cleansing; the sewers laid under the bustee roads provide facilities for efficient drainage when the various groups of huts are properly and fully connected.

"Besides the above, the work of reconstruction is also in progress in—

	Area.
Nather Bagan - - - - - -	16 bighas.
Colvin's bustee - - - - - -	56 "

and measures have been taken to bring the following eleven bustees under the operation of Sections 280–283 :—

	Area in Bighas.		Area in Bighas.
Kalakur - -	5	Parseebagan - -	20
Phoolbagan - -	7	Soorhatta - -	3
Pathuriaghata - -	9	Keraneebagan - -	24
Lalbagan - -	17	Kristobagan - -	45
Shaikpara - -	4	Ooryapara - -	25
Kaloo Ghose's Bagan -	24		

"In order to facilitate the reclamation of bustees, the legislature in 1881 conferred on the Corporation the power of acquiring them for the purpose of improving them, and during the current year this provision of the law has been acted on in the case of a portion of the Jorabagan bustee. That bustee is now in process of being entirely remodelled.

"In addition to the reclamation of bustees under Sections 280–283, the corporation have recently entertained special establishments for surface cleansing in the manner attempted by Dr. Payne in 1877. This bustee establishment began to be organised from the commencement of the year 1883–84, and the greater portion of the bustees have now been taken in hand and are being cleaned by its agency. This subject will be more fully treated when we come to discuss the recommendations we have to make.

"In the matter of general conservancy the Commissioners have introduced several improvements of greater or less importance. In 1877 the Corporation organised a municipal *halalcore* or latrine service, in place of the tola mehter system which existed formerly. The matter will be treated at length when we come to discuss the latrine system, but it is perhaps not too much to say in this place that, with the present insufficient water supply, this reform may be reckoned among the greatest boons ever conferred upon the town. For some time past again, the Corporation have been pursuing, with more or less energy, the policy of filling foul tanks in bustees, with the result that, in the last eight years, no fewer than 178 such tanks have been obliterated. Within the last three years the cleaning of the sewers has received special attention, and been placed on a more efficient footing. A system of inspection of house drainage connections has also been organised. The hackney stables have been passed and drained, and determined efforts made with more or less success to improve the disgraceful state of the cowsheds in gowalla bustees. The

conservancy arrangements have been further improved by the organisation of an experimental service for removing the droppings of horses and cattle from the public streets during the day. And latterly the Commissioners have shown some energy in constructing bathing platforms to provide the means of ablution in place of the large number of tanks which have been filled or the water of which has been condemned. These may not all be great measures of reform, and some of them may perhaps be found not to go far enough; but they have all tended to improve the sanitation of the town, and deserve to be fully taken into account in considering its present condition. They will accordingly be referred to at greater length hereafter, when we come to treat of the recommendations we have to make."

With this evidence of the gradual improvement that has been effected in the sanitary condition of the town before us, it would be manifestly incorrect to ascribe the augmentation of cholera to progressive insanitation. Intensity of cholera in a particular area may be said to depend on three main factors, viz., local insanitation, personal receptivity on the part of the population, and climatic causes. Local insanitation is certainly, as the experience of this city teaches, the chief and most potent agent in producing the disease, and that this condition still prevails to a wide extent in the native part of the town is a fact but too well known. But the state of things was equally bad, indeed it may be affirmed, certainly worse, in the years when the intensity of cholera was at a minimum. The second factor, viz., personal receptivity on the part of the populations remains the same as in former years. The population of the town, now as then, is largely recruited by immigrants from districts in which cholera is not endemic, and these form a class, as the mortuary returns of the town show, highly susceptible to cholera. We are then driven to seek in the last factor, viz., general climatic causes, for the explanation of the increase in the prevalence of the disease in late years. The influence of this factor can be determined by contrasting the mortality from cholera in Calcutta for a series of years with that of the neighbouring towns and districts. Allowing, as we may fairly do, that the sanitation of these places does not vary much from year to year, we nevertheless find that the amount of cholera varies greatly in different years. The accompanying diagram (not reproduced in this abstract), which I have extracted in part from the report of the Commission above referred to, illustrates the comparative intensity of cholera in the districts of Lower Bengal lying close to Calcutta, viz., Nuddea, 24-Pergunnahs, Howrah and Hooghly, including Serampore and in the town of Calcutta, Howrah and the suburbs for a period of eight years. This diagram to my mind shows very clearly that, other things being equal, the intensity of the disease in the town from year to year is regulated to a very large extent by general climatic causes which affect equally the large tracts of country comprising the neighbouring districts. If one were to examine the town figures alone, he might be inclined to attribute the increase of cholera to some local cause, to think that perhaps it was connected with the filling of the tanks, or that it was due to the extension of the system of underground sewers, or to the introduction of unfiltered water from the river into the bathing platforms, or to some other cause operating within the confines of the town, but a glance at the diagram would refute such theories and show that the intensity of cholera from year to year is mainly regulated by causes which govern equally the distribution of the disease in districts in which no such conditions exist.

Thus in 1878 we find that the disease prevailed in the four areas selected for comparison at a high level, highest in the suburbs, high in Howrah, much lower in Calcutta, and still lower in the rural tracts of the neighbouring districts. In 1879 we find a marked descent in all four, but the relative levels are maintained. In 1880 there is a still further descent, and the disease is everywhere at a minimum. In the four succeeding years we find a steady increase with one intermission in all the areas, until the highest point is reached in 1884. Both in increase and in intermission the relative levels are maintained. The diagram appears to illustrate very clearly the influence of general climatic causes, and to show that the increasing prevalence of cholera in the town of late years has been due mainly to them.

It is satisfactory here to be able to state that in the present year 1885 cholera shows a tendency to assume a more favourable course than that which it maintained in 1883 and 1884. The deaths in the first five months of the year, as compared with these years, were as follows:—

	January.	February.	March.	April.	May.	Total.
1883	204	129	227	490	393	1,443
1884	36	123	486	847	283	1,775
1885	79	153	242	356	147	977

From these figures it would appear to be safe to augur that cholera is about to return to the more moderate proportions of the earlier years of the decade. The lesser mortality of the present year, I have no hesitation in saying, is due in a great measure to more favourable weather. In 1884 there was a great drought and intense heat; in the first four months in the present year, the heat has been tempered, and the surface moistened by seasonable showers, and the wind has blown more frequently from the north.

As regards the localisation of cholera, the densely crowded and insanitary riparian wards of Jorabagan and Burra Bazar suffered most, the death-rate being 9 and 7·9 per 1,000 of population, while the mortality in the whole town was 5·2. The rate in these wards was also comparatively high in the decennial period. They are pre-eminently stranger's wards, being to a very large extent occupied by immigrants from up-country who come into the city for purposes of trade. For instance, the population of Jorabagan is composed of 24,324 males and of 11,994 females, and of the males nearly 18,000 or 70 per cent. are at what might be called the business-age, that is, between 20 and 40. In Burra Bazar the disproportion between the sexes is still greater, viz., 16,122 males and 4,647 females, and the proportion of males between the age of 20 and 40 is the same as in Jorabagan. This shows to what a large extent the population is non-resident. It is chiefly immigrant and fluctuating and reinforced by frequent additions from outside. From the Census Report of 1881, I find that only 11 per cent. of the population of Burra Bazar are natives of Calcutta, and of Jorabagan only 18 per cent. A population of this kind is, as I have stated in a previous paragraph, highly susceptible to the endemic influences which cause cholera. The following statement, which I have received from Dr. Sanders, the Superintendent of the Mayo Hospital, shows to what an enormous extent new arrivals in the town fall victims to these fatal influences:—

Cholera Cases admitted and died during the Year 1884 *in Mayo Hospital, Calcutta.*

Year.	Under 3 Months.		Over 3 and under 6 Months.		Over 6 Months and under 1 Year.		1 Year and over.		Total.	
	Admitted.	Died.	Admitted.	Died.	Admitted.	Died.	Admitted.	Died.	Admitted.	Died.
1884	179	77	39	19	43	16	75	38	336	150

The total number of cases of cholera treated in the hospital in 1884 was 336, and of this number 261 or 77 per cent. were residents in the city for less than one year, and 179 or 53 per cent. were residents for less than three months. I have extended the same inquiries in other directions with the result of confirming the experience gained in the Mayo Hospital, and of showing in what a remarkably high proportion strangers in the town suffer from cholera.

Next to Jorabagan and Burra Bazar, Hastings, Coomertolly, Shampooker, and Burtollah suffered in proportion to population, the mortality varying from 6 to 7 per 1,000. In Jorasanko, Sukea's Street and Colootollah the mortality was also high, the rate ranging between 5 and 6 per 1,000. In the southern wards the mortality was comparatively low.

Bowel complaints.

The registered mortality from dysentery and diarrhœa was unusually low during the year. The total number of deaths from these diseases is less than that of all the years of the preceding decennium and 344 less than the mean of the decennium. In other years when cholera prevailed at a high rate, diseases of this class were also rife; but the past year forms an exception to the rule, for, with a high cholera mortality, we find a great reduction in the number of deaths from bowel complaints. It might be suggested in explanation of this fact that some of the deaths due to bowel complaints were registered as cholera; but this would be merely a surmise incapable of proof. We must take the figures as we find them, and believe that the mortality from bowel complaints as well as that from fevers was at a low ebb during the year.

Small-pox.

Under small-pox 478 deaths were registered, a larger number than has been registered in any year since 1879. The history of Calcutta shows that it has been periodically visited by epidemics of small-pox. Statistics show that an outbreak more or less severe occurs every four or five years. The last great epidemic occurred in 1878-79.

In these two years the deaths amounted to 2,267. In former epidemics the mortality was much greater. Thus in the great epidemics terminating with that of the years 1864–65, the average number of deaths was 3,873, whereas in the later epidemics of 1874–75 and 1878–79 the average fell to 1,583, or less than half the mortality of the earlier epidemics. Another fact is noticeable with regard to these epidemics, viz., the more severe the visitation the longer and more complete the period of immunity that ensued. For instance, the great epidemic of 1849–50 with 6,154 deaths was followed by five years in which the average number of deaths from small-pox was 56, and the outbreak in 1864–65 in which 5,556 persons died, was followed by a lull of eight years in which the annual average was 54. On the other hand, after the milder epidemics of later years, epidemics that have been mitigated and curtailed by vaccination, the period of immunity, as might naturally be expected, has been neither as long nor as complete. For instance, the epidemic of 1874–75, in which 900 deaths occurred, was followed by only two years of comparative freedom from the disease. In 1878–79 it broke out again, and slew 2,267 persons. In the four succeeding years, 1880 to 1883, the average annual number of deaths exceeded 80, and the disease again assumed an epidemic form in 1884. The fact would appear to be that a severe epidemic visitation of small-pox protects the town in a more thorough and complete manner than a mild epidemic does, even with the aid of augmented vaccination. A severe epidemic attacks all, old and young alike, whereas vaccination, with the help of which and segregation recent epidemics have been stamped out, has been confined chiefly to the protection of the young. The Compulsory Vaccination Act aids mainly in securing this result, but up to the present no efficient means have been devised of securing the protection of the thousands of adult emigrants who swarm into the city year after year either for permanent or for temporary residence. Even with the aid of the increased vaccine establishment sanctioned last year, it was found most difficult to push vaccination to any great extent among people of this class. But the importance, nay the necessity of doing so, may be gathered from the following figures. During the past year 451 cases of small-pox were reported by the Police and by the Inspectors of Burial Grounds and Burning Ghats. Careful inquiries were made in each case by the officers of the Vaccine Department, and it was found that out of the total number no less than 335 or 74 per cent. were immigrants, and had been dwelling in the town for less than one year. These figures are conclusive in showing to what a large extent outbreaks of small-pox are due to the immigration into the town of unprotected persons from outside. It will be always most difficult to secure the complete vaccination of people of this kind, or even to ascertain their existence unless a Census is made from time to time for the purpose of ascertaining the state of protection of the population against small-pox. The house-to-house visitation and inquiries which have been recently introduced fail to a great extent. In huts and lodging houses, for instance, the male occupants are, as a rule, absent at work during the day, and adult females object to examination, so that numbers of unprotected persons escape the inquisition of the vaccinators. From year to year unprotected persons of this kind accumulate, until at length the pabulum of an epidemic is provided.

Other causes.

There is not much to remark under other causes of mortality. The total number of deaths registered was 5,679, against 5,253, the mean of the decennial period. Three years, viz., 1880, 1881 and 1882 show a large number of deaths from "other causes" and seven a smaller number. It is difficult to explain the variation of these figures from year to year.

Vaccination.

The number of persons vaccinated during the year was considerably in excess of the average of former years. The increase of small-pox in the hot weather caused much alarm, and gave rise to the idea that a severe epidemic, rivalling those of former years, was at hand. Accordingly on 23rd May, at the request of the Health Officer, 6 extra vaccinators were sanctioned by the Commissioners for 2 months, and at the end of this time, viz., on 23rd July, the following permanent additions were made to the vaccination establishment, viz.:—

1 Assistant Superintendent, a qualified medical practitioner.
1 Female vaccinator for work in zenanas.
7 Vaccinators.

The vaccination establishment of the town now consists of—

1. The Deputy Superintendent.
2. The Assistant Superintendent.
3. 21 Vaccinators.
4. 1 Female vaccinator.

Thus we see that the establishment has undergone an increase of 50 per cent. during the year.

The outturn of work resulting from this increase has been satisfactory in a high degree.

The numbers vaccinated in the town for the past 5 years were as follows:—

	Vaccinated.	Re-vaccination.	Total.
1880	5,349	1,398	6,747
1881	5,522	1,016	6,538
1882	7,273	529	7,802
1883	8,649	2,450	11,099
Average	6,698	1,348	8,046
1884	13,571	2,092	15,663

From this statement it is seen that the total number of vaccine operations performed in 1884 were almost double the average of the 4 preceding years, and in the case of primary vaccinations the number was more than twice the average. The statement is also instructive in showing the steady and rapid progress that vaccination is making from year to year in the town. We have, however, now reached a figure which I do not think it will be easy to exceed or even to sustain in future years. The primary vaccinations last year were over 50 per cent. in excess of registered births; in other words, this number of unprotected persons (mostly children) were sought out and vaccinated. But it is obvious that this process cannot go on continually. The number of unprotected children must, under the present system, decrease from year to year, and so eventually must the number of vaccine operations.

The peculiar feature of the work last year was, that it was pushed on with equal vigour all the year round without the interruption of a recess in the hot weather and rains as in former years. In the hot weather, when small-pox was prevalent, bustee vaccination and vaccination in the immediate neighbourhood of infected houses was enforced as far as possible. With regard to vaccination in the months from April to September, I can state from the observation of large number of cases that it runs almost precisely the same course, and is as safe and as efficient in the protection which it confers as vaccination in the cold weather. In fact the experience gained last year goes to prove that the popular prejudice against vaccination in the hot weather and rains is altogether unfounded. 4,940, or close on a third of the total number of operations in 1884, were performed between April and September.

Notwithstanding the considerable increase made in the vaccination establishment, it is satisfactory to be able to report that the actual cost of each vaccine operation was less than in the previous year. The average cost of each successful case was 8 annas against 9 annas 7 pie in 1883, and if the fees realized by home vaccination be deducted from the total expenditure, the cost of each case is 7 annas 2 pie, against 8 annas 10 pie in 1883.

With regard to the character of the vaccine work I may say that I made regular weekly inspections of the vesicle, and found it as a rule excellent. The lymph was frequently renewed from the calf, and typical vesicles were the rule. The habit is to vaccinate with two spots on each arm. In probably 90 per cent. of the cases four spots were successful, a high per-centage no doubt, but not surprising when it is remembered that arm-to-arm vaccination or vaccination direct from the calf is always practised. Neither tubes, glasses, nor points are allowed.

Sanitary work.

The improvement of bustees occupied a good deal of attention during the year, and several large bustees were taken up for structural and sanitary improvements. The projects for improving them are under consideration, and will be carried out in due time. No more useful sanitary work can be undertaken than that of remodelling and improving these extremely crowded and ill-drained localities.

The surface cleanliness of bustees was efficiently maintained by the staff of coolies and dhangurs employed for this purpose by the Corporation.

Drainage.

Much attention has been devoted to the drainage of bustee lands. In the smaller bustees, and blocks of huts where drainage is defective, notices have been served on the landlords requiring them to improve the drainage of the land. A large amount of drainage has been carried out in this way, and the work is being pressed on every day.

One steady object has been held in view throughout the year, viz., to confine sewage in surface drains of masonry falling into the sewers, and to prevent as far as possible its escape over the surface. In every part of the town work of this kind is in progress.

Nuisance department.

The following return will show the work done by the Nuisance Department as far as privies are concerned :—

Number of privies on the revised list - -	28,913	
Do. undertaken - - -	1,172	
		30,085
Less number in which services discontinued - -		511
Total number now served - -		29,574

Many difficulties have been encountered in demolishing and remodelling old privies of faulty construction, and in having new ones built on the standard plan to replace them.

Pipes or service drains with cement plastering or pointing have been insisted on in all cases to prevent the escape of urine and washings from privies and to convey them to the sewers. The people of the lower classes can with difficulty be got to understand the advantages of these drains, and they place many obstacles in the way of their construction, chiefly on the score of expense. However, obstruction has been steadily overcome, and privy drains in large numbers have been connected with the sewers, either singly or by a joint operation on the part of contiguous hut-owners. In fact these drains, now rapidly extending, form a prominent feature in every bustee. In cases where the sewers are at too great a distance from bustees, and in those parts of the town which are yet undrained, *e.g.*, Hastings and Bagh Bazar, mason receptacles for washings from privies are allowed. The receptacles are cleaned daily, and the liquid sewage matter thrown into the nearest discharge depôt.

In connection with the Nuisance Department work 68 foul wells were closed in private premises during the year. Privies are not allowed to be constructed within 20 feet of a well; so to obtain the necessary sanction for the construction of new privies, many wells in small-house premises had to be closed. When the additional supply of filtered water reaches the town, it is to be hoped that a law will be introduced compelling the closure of all the wells in the town. At present it would be premature to close all the wells, as the supply of filtered water is inadequate to the wants of the people in many localities, and water of some kind has to be used for washing clothes, cooking utensils, bathing and many other domestic purposes. In fact, if all the wells were shut up at present, a very large amount of the water necessary for keeping the sewers in order would be withdrawn. But when the new supply of filtered water reaches the town, all objections to the closure of wells will be removed, and vigorous measures should be taken to obliterate them. The water in these wells, as has been frequently pointed out, is most impure, and on analysis gives results worse than ordinary sewage.

The work of dewatering and filling tanks has been vigorously carried out during the year. On the requisition of the Health Officer several foul tanks were dewatered. The total amount of work done in this direction during the year was as follows :—

(1.)	Number of tanks on the condemned list -	50
(2.)	,, dewatered - - - -	9
(3.)	,, filled with refuse and earth - -	20
(4.)	,, being filled at end of year - -	17

The number of tanks filled in a particular year depends entirely on the size of the tanks; hence, though the amount of work actually done may be the same, the number of tanks actually filled must vary greatly from year to year.

In connexion with the filling of tanks, the question of bathing platforms naturally arises. The filthy tanks have hitherto been used almost exclusively by the lower classes for bathing purposes. As they get obliterated it becomes absolutely necessary to provide other water for bathing. Several bathing platforms were constructed during the year, and at the close of the year 30 were in working order. The Commissioners have sanctioned the construction of an additional 30 platforms in the current year, and the Health Officer has been asked to select sites for them. Some 50 suitable sites have been chosen, and out of these 22 have been selected for the immediate construction of platforms. The remaining eight sites will be fixed in the localities which need them most.

The platforms are fed by water pumped every day from the river. They are the greatest possible boon to the people, and are immensely appreciated by them. Numerous petitions and applications asking for platforms in particular localities have been received during the year. I have had a census made of the number of bathers in some of the platforms, and I find that the average is from four to five hundred people per diem in each. When the additional supply of filtered water reaches the town, it is to be hoped that a sufficient quantity will be available to feed the platforms. The water pumped into them from the river opposite the town, though infinitely better than average tank water, is by no means pure. In fact, it does not come within the class of potable water, and, considering the reckless habits of the lower classes, I think none but a water that may be drunk with impunity should be supplied in the reservoirs of the platforms. During the cold and dry seasons, extending from November to May, the river water near the town is highly brackish, and its use predisposes to attacks of diarrhœa and cholera.

Considerable attention has been paid to the improvement of the numerous filthy, badly drained, over-crowded cowsheds which exist in various parts of the town. A large number of these sheds, especially in the southern wards, have already been improved, and are extremely clean and well kept; the cattle stand on floors of wood or masonry, and the drains are in good order and connected with the sewers; but in the northern and central wards a large number are still in a very defective state. There are altogether about 550 sheds for milch cows in the town. Of these over 300 have now been connected with the sewers by means of brick drains. During the past year 88 sheds and premises have been improved in the matter of drainage, sewer connexion, and flooring of the stalls. Masonry receptacles or chowdachas have also been constructed in 42 sheds, and notices have been served in several other cases in which the work is not yet complete.

The Inspector appointed to the special duty of improving the sanitary condition of Jorabagan and Burra Bazar organized a self-supporting establishment, which did much useful work without any cost to the Corporation. The owners of premises found in a filthy state were ordered to have them cleaned out under pain of prosecution, at the same time the Inspector gave an estimate of the cost of the necessary work, and in a large number of instances he was asked to get it done by the self-supporting establishment. The total amount received for work of this kind from July 1884 to 31st March 1885 was Rs. 1,134. Work of a similar kind is now carried out by the other Inspectors: but there are few parts of the town in which houses and house enclosures are found in such a filthy state as they were in Jorabagan and Burra Bazar when we commenced work in July.

ABSTRACT OF REPORT OF THE MADRAS MUNICIPALITY FOR 1884-85.

(Mr. G. T. Mackenzie.)

Drainage.

The pumping station at Royapuram was formally opened by His Excellency the Governor on June 30th, 1884. The drainage from the eastern and north-eastern sections of Black Town, and also the sewage taken from the main drain near the Fort by the pumping engine into the intercepting sewer, flows to this spot and is raised and delivered through a two foot main, nearly one mile in length, to an open elevated channel which leads it northwards to the sea. Very little sewage escapes into the sea. Almost all is supplied as a fertilizer to the land on either side of the channel.

Difficulties were experienced in the work of constructing the sewers which form portion of the Black Town scheme. The heavy rains of 1883 caused an excess of water in the subsoil, and the rains of 1884 in Madras were worse and seriously impeded the works in progress. Sewer No. 1 was commenced in March 1884 and 2,012½ feet were constructed. In sewer No. 2, 510 feet of 12-inch pipe, 3,822 feet of 18-inch pipe, and 1,003 feet of two foot brick sewer were constructed. The work has been inspected by several officers of the Public Works Department. The nature of the soil and the enormous flow of water will increase the cost much above estimate, but no way of escaping this expense suggests itself.

The surface drainage of the eastern portion of Black Town between Popham's Broadway and the sea is almost complete. More than 70,000 feet of surface drain were laid during the 15 months, while 489 house drains were altered by the municipality and 1,316 by the owners. The opportunity has been taken to widen and improve several streets.

Diversion of Drains from the Cooum.—In Poodoopett a plot of land measuring more than 22 acres was purchased and, a parcherry being removed from it, was levelled to serve as a sewage farm for the disposal of the contents of a large drain which flows into the Cooum.

Water supply.

Advantage was taken of the low level of water in the Red Hills Lake to commence the off-take tower in the deepest part of the lake, which is portion of the new water supply scheme for a supply by pipes from a filtration bed at Red Hills. This work was executed from the Rs. 75,000 which Government contributed. It was pushed on vigorously, and since the commencement of the current year the machinery has been received from England and the work has been completed.

Extensions of the existing water-supply were made to Royapuram and Cassemode and a larger main was laid in Monegar Choultry Road, at a cost of Rs. 6,768.8.9.

The cyclone of the morning of November 21st completely breached the Red Hills Reservoir and the whole supply of water was lost. For 10 days the city had only a partial supply from Trevelyan Reservoirs and the Seven Wells, aided by rain water from the Red Hills channel, but on December 2nd water from Koratur tank was led into this channel and a supply was thus obtained until February 2nd, when the temporary bund erected at Red Hills by the Department of Public Works raised the water above the level of the off-take pipes and again supplied Madras with Red Hills water.

Although it does not fall within the period under report, it may be convenient here to mention that in May the water fell below the off-take pipes and since that date has been raised by steam pumps, three engines being kept working night and day. The cost of this and of the previous operations at Koratur has been debited to Temporary Water Supply, and remains to be adjusted, there being no Budget provision.

Conservancy.

The expenditure on conservancy in 1883 was Rs. 2,42,531.5.11, and in 1884 Rs. 2,53,093.3.1. The increase arose chiefly from the expenditure on the new pumping station at Royapuram and on the salary for six months of a Special Sanitary Officer.

The expenditure during the 15 months was Rs. 3,28,550.8.3. In cleaning the main drains Rs. 8,688.11.9 were spent, and this exceeds the estimate, the reason being that the heavy rains at the close of 1884 filled the drains with silt to an extent much in excess of the amount expected, and when this silt was removed the actual work done at a fixed rate per cubic yard was paid for. The item of Rs. 3,750 in the Budget for repair of carts, boats, and buckets was exceeded, the expenditure being Rs. 4,410.10.5. This was caused by an emergent expenditure of nearly Rs. 1,000 in the repair of the nightsoil barges on the canal. The expenditure on contingent charges was Rs. 5,261.7.1 in 1883 and rose to Rs. 7,491.9.0 in 1884, and to Rs. 9,090.3.8 in the 15 months. One cause of this increase was the cost of clearing silt from the canal basin and certain street drains, which alone amounted to nearly two thousand rupees.

The system of conservancy followed did not differ from that of previous years. 1,189 coolies, 598 carts, and 6 canal barges were employed, and removed 462,984 cart loads of rubbish and silt and an amount, estimated at 63,354 tons, of nightsoil. The fourth, fifth, and eighth divisions are yet without any system of house conservancy. It is very necessary that house conservancy be extended, as soon as possible, to Vepery, Royapettah, and St. Thomé. The real difficulty in maintaining a proper system of conservancy in Madras arises from the unruly temper of the scavenger class, as is pointed out by Surgeon Davis in his report. This difficulty is increased by the fact that the men are not paid by the municipality, but by the labour contractor who supplies them. Because of any shortcoming the municipality fines the contractor, but this does not affect the men, who continue their unruly conduct. What is wanted is that the men should be employed directly by the municipality, and that some legal enactment, similar to section 490 of the Penal Code, should render a refusal to work penal.

Sewage farms.

The sewage of several drains which formerly flowed to the beach or into the Cooum or canal, poisoning the air, is now lifted or led on to grass lands where it is deodorized by the sun. This system is pursued solely on sanitary grounds and would be continued even if the financial results were unfavourable, but a profit results from the sale of grass to private persons and of hay to the Body Guard and to the batteries at the Mount. The net profits in 1883 were Rs. 478.10.0 and during the 15 months were Rs. 744.4.7, and would have been higher had not the heavy rains caused damage.

Vaccination.

The expenditure on vaccination in 1883 was only Rs. 5,601.8.0, but in the 15 months it amounted to Rs. 14,105.12.5. The increase arose from the steps taken to facilitate vaccination in consequence of the epidemic of small-pox which prevailed from June 1883 to June 1884. Section 378 of Act I. of 1884 enabled byelaws to be passed making vaccination compulsory, and, accordingly, byelaws were framed and came into force on June 1st, 1884. In each division of the city there is a depôt where vaccination is performed without fee. In five of these depôts the vaccination is from the calf. The total number of cases vaccinated was 28,030 in 1882, 40,940 in 1883, and 66,507 in the 15 months. The per-centage of successful cases fell to 83·6, which is not quite satisfactory, but matters improved at the close of 1884 when Surgeon Davis and Deputy Inspector Jesudasen Pillay supervised the work, and strict supervision will no doubt maintain the improvement. One good feature in the work of the 15 months is that the number of infants vaccinated is close upon the number born. If this can be maintained there will be little cause to fear the next periodical outbreak of small-pox.

Vital statistics.

The birth-rate per 1,000 was 3·98, as compared with 41·2 in 1883, 42·7 in 1882, and 40·3 in 1881. The total number of births in the 15 months was 19,845, of which 415 were still-born, or almost 2·1 per cent. The per-centage of male and female births was 51·09 and 48·91.

In 1883 the number of deaths was 15,882, making a death-rate of 39·8 per 1,000. In 1884 the number of deaths was 20,123, or 50·48 per 1,000, and in the 15 months the number of deaths was 24,482, which is at the rate of 49·11 per 1,000 per annum. Of these 24,482 deaths, 4,074 were from small-pox and 1,358 from cholera. If the loss from these two causes be omitted the death-rate is only 38·2. The epidemic of small-pox was very severe in the opening months of 1884, the deaths in each month being January 798, February 1,111, March 1,238, April 524, May 211, June 78. Cholera decreased in these months, almost disappearing in June and July, only to break out with increased virulence in August, and in September there were no less than 573 deaths. It was still present up to the close of the 15 months under report.

The system of registration of deaths is not satisfactory, but it is difficult to suggest where improvement can be introduced. In Britain the cause of death is certified by a medical practitioner. In Madras the cause of death entered in the register is whatever cause is alleged by a relative, often ignorant of diseases and their classification. In some instances inquiries are made by the Health Officer or his subordinates, but this can be done only in a small number of the cases reported. One point may be mentioned in this connexion is that an extract from the municipal register is accepted as proof of death by the numerous societies that have recently sprung up over Madras. This does not concern the municipality, and the extract may be evidence that a death has taken place, because the register is checked with the returns from the burial and burning grounds, but it is not good evidence of the cause of death.

The deaths from different causes in 1883 and in the 15 months are here shown :—

	1883.	1884-5.
Small-pox	1,957	4,074
Measles	138	146
Fevers	3,470	4,863
Cholera	169	1,358
Bowel complaints	2,284	3,459
Other causes	7,864	10,582
	15,882	24,482

ABSTRACT OF REPORT OF THE MUNICIPAL COMMISSIONER FOR THE CITY OF BOMBAY FOR 1884-85.

(Mr. E. C. K. Olivant.)

In the Municipal Commissioner's Report for last year the reasons for laying a new 24″ main from Vehar to supply the northern and outlying districts of the city, and to carry the supply which could not be conveyed to the Bhandarwada Reservoir, were fully detailed. This main has now been laid as far as Kurla, where it is connected with the 32″ main to Bhandarwada, and the work of completing it between Vehar and Kurla, and of constructing filter beds at Vehar, is being pushed on. The connexion between the 24″ and 32″ mains at Kurla was only made on 6th April last, and the subject comes, therefore, more properly within the scope of next year's report; but I may mention here that the anticipated result was satisfactorily realized by the diminution and, indeed, almost total absence of the usual hot weather complaints of want of water in the Vehar districts. Mr. Braham reports that the 32″ main, owing, he supposes, to internal corrosion and incrustation, and the friction that is caused thereby, does not deliver as much water into the Bhandarwada Reservoir as it is theoretically capable of discharging, and he compares its actual capacity with that of a 30″ main. This is an additional reason in favour of the 24″ main direct from Vehar; and when this is completed there can be no doubt that the whole available supply from the Vehar Lake will be drawn off, increased as it is by the new catch-water channels which were completed in time to be brought into use before the monsoon of 1884, and which materially increased the quantity of water impounded. Supply.

The work of raising the Tulsi dams and constructing new catch-water channels is now practically completed, sufficiently so to impound and retain the water of this year's monsoon.

The Bhandarwada Waterworks are now completed. Mr. Braham accords considerable praise to all the contractors concerned, and their work was on the whole well done.

The filter beds at the Malabar Hill Reservoir were completed during the year under report, and have been in use during the whole year. The roofing of the reservoir is in progress. The filter beds will in a short time be completely roofed in. The water supplied to the Tulsi districts during the past hot weather was very much better than any that has ever been supplied to them before. When the roofing of the Malabar Hill Reservoir is completed and the new 24″ main laid from Vehar it will be safe to say that the quantity and the purity of the water distributed over the city are as ample and as perfect as it is possible to make them with the present sources of supply.

This leads me to the subject of the Tansa project, which cannot be passed by without some reference, though it can hardly be said to fall to any extent at all within the scope of the present report. The corporation sanctioned, on 27th November last, a grant of one lakh for the Tansa survey, and the work was begun by Mr. W. Clerke, Executive Engineer, whose valuable services were put at the disposal of the municipality by Government for the purpose on 27th February 1885. It is as yet premature to enter into any of the details of the project, but I may safely say that if it be carried out, the difficult question of water supply to the present city of Bombay and to any possible future Bombay will be set at rest finally and for ever.

The contractor for the supply of Deacon's patent differentiating waste water meters engaged to despatch an efficient superintendent to supervise the fixing of them and to train the staff required for working them. The superintendent arrived in Bombay at the end of December last. Eighty-six meters were fixed in the year under report. It is expected that the advantage derived in the prevention of waste will be great. In those towns where they have been adopted they are most highly spoken of, and when I was in England I had opportunities of judging of the excellent results obtained from them both in Liverpool and Glasgow. The duty of preventing the improper waste of water, especially when the quantity available is so restricted as it is in Bombay, and will be till the Tansa project is carried out, comes next in importance to the duty of securing an adequate supply, and the finances of the municipality will be very far from suffering from expenditure to that end.

The total number of water connexions has risen from 13,545 in 1883-84 to 13,909 in the year under report. The aggregate length of the mains examined by the Waste Prevention Staff was 34,945 feet, and leakage to the extent of 250,000 gallons per diem was discovered and checked. This staff is at present under the orders of the superintendent for fixing Deacon's meters.

Drainage.

Mr. Walton reports the final settlement with the contractors of all claims, &c., relating to the laying of the pipe sewers in the first portion of the drainage scheme. He also reports that from the absence of means for admitting the house sullage to these sewers they are practically useless. This subject, which has frequently been pressed on the attention of the corporation, was, at the end of the year under report, still being considered by a committee which was appointed to consider whether the necessary house pipes and fittings should be paid for by the municipality as at first determined, or by the house owners. It is very advisable that the construction of pipe sewers throughout the city should be pushed on, nor is there any reason why it should be delayed pending the settlement of the question whether the cost of the house connexions is to fall on the municipality or on the house owners. Whatever decision on this head be arrived at will not affect the necessity for the construction of pipe sewers. Until the system of branch sewers is complete the nuisance on the flats will not and cannot cease to exist. The new main sewers being designed only to carry sewage, to the exclusion of storm water, have necessarily to be disconnected during the rains from the old branch sewers which carry both. During the rains, therefore, the greater portion of the sewage of the city (the whole except what is put into the new system at the nightsoil depôts) finds its way into Back Bay and the harbour at the old outfalls, or into the old main drain. Whatever goes into the latter floods the flats more or less over the site of the future surface drainage reservoir. Were the system once completed, the old main drain would be used exclusively for carrying the storm waters, the whole of the sewage going by the new main drain to the pumping station, and the flats would cease to be a nuisance.

The completion of the Queen's Road intercepting sewer was noticed in para. 62 of the Municipal Commissioner's last report, though it fell within the year now being reported on. It will be remembered that a bonus was offered to the contractor at his suggestion if he would complete the work by the monsoon of 1884, instead of in February 1885, and though those terms were agreed to, and for the more speedy prosecution of the work the Queen's Road was opened up, much to the inconvenience of the public for a long distance, the contractor virtually threw up his contract on the 14th April 1884. The work was then undertaken departmentally, and so vigorously was it pushed on that by the 2nd July it was completed, though it involved the construction of no less than 5,180 feet of ovoid sewer. Great credit is due to Mr. Walton for the remarkable energy shown in the completion of this work; and he speaks very highly (and deservedly so) of several of his subordinates. By the construction of the Queen's Road intercepting sewer and the marine lines pipe sewer in continuation of it, which was also constructed by departmental agency during the past season, the nuisance arising from the outfall of sewage in Back Bay is over, except during the rains. In the monsoon, as has been already explained, the old outfalls have to be resumed, because the old branch sewers, carrying storm water as well as sewage, have then to be detached from the new Queen's Road intercepting sewer, which is designed only for sewage. For the pipe sewerage system connected with the Queen's Road drain the requisite surveys have been made, and plans and estimates prepared, and this subject will shortly be brought before the corporation. I should observe, however, that the abating of the Back Bay nuisance is also partly due to the construction of the pipe sewer from the Girgam nightsoil depôt to Queen's Road sewer, which was carried out during the year under report, and by means of which the outfall of sewage on to the foreshore of Back Bay, west of the level crossing, has been stopped.

The extension of the Clerk Road sewer from the Central Station to the Parel Road proceeded satisfactorily, and will be completed within the contract time. The progress of the DeLisle Road 18" pipe sewer was delayed by the rock blasting required, and the Arthur Road 15" pipe sewer, which is to be connected with it, has been retarded by the same cause, but it could in no case be used till the DeLisle Road sewer is ready for use, which Mr. Walton anticipated would be by 15th June.

The work of constructing ovoid sewers from the Crawford Market to the Mint and along the new Ripon Road has proceeded as rapidly as the difficulties caused by rock excavation in the former case, and by making terms with the owners of land in the

other would allow. The work of laying pipe sewers in the Agripada district has been kept well in hand, and Mr. Walton anticipates its completion within the contract time. The work of fixing the house sullage connections in Kamathipura was begun at the end of October last, and was carried on till the close of the year.

Turning to the subject of surface drainage, which is so intimately connected with the sewerage scheme that the two must always be considered together, the first thing to observe is that the greater portion of the Mahalakshmi storm-water reservoir has been excavated down to the required level of 77 T.H.D.; the banks have been constructed as far as the excavated material would allow; and the completion of the whole work is anticipated by the 31st December next. The diversion of the Tulsi pipe line has been effected. But as was observed in my annual report for last year, "it is very evident "that the channel which conveys the rain water to the reservoir should not also be a "carrier of sewage." But so it will continue to be until all the sources of sewage in the city are connected with the new main drains. Till this is done, the old branch sewers must be used. The connection of these with the new main sewers presents no difficulties during the fair weather, but as soon as the rains commence, they must be detached and reconnected with the old system. The old main drain, therefore, during the rains continues to pour sewage as well as storm water over the Flats, that is, over what will be the surface drainage reservoir, and thus at present there can be no abatement of the nuisance on this part of the Flats.

The Gowalia Tank, Tardeo, and Arthur Road storm-water drain has been completed, and the flooding of the low-lying parts of the city about Khetwadi has been materially relieved. The storm-water drain from Bellasis Bridge to the point where Bellasis Junction Road meets Parel Road has been completed with the side entrances and water entrances thereto. The section from Bellasis Junction Road to Jail Road is now in progress; it is rendered difficult by the small space to spare between the tramway line and the gas main. The surface drainage of Kamathipura has been completed. Mr. Walton draws attention to the necessity of providing an improved outlet for the storm-water of the Parel and Chinchpokli neighbourhoods.

The discharge of the night-soil that used to be pumped into the harbour at Carnac Bandar into the new main sewer at the same place is one of the chief features of the year's administration. The pumping arrangements have been so designed by Mr. Walton as to cause a minimum of offence on the spot. The whole of this night-soil is now carried away to the Love Grove Pumping Station, where the engines have worked very well throughout the year, though neither so well nor so economically as they will work when the improvements and additions which are being made are completed. The chief of these is an extra condensing tank which has been rendered necessary since the number of engines has been increased from two to four. The total quantity of sewage lifted during the year was 11,883,274-8 tons, at an expenditure on coal of Rs. 26,503-0-6, which was well within the Budget allowance. I may mention here, though it is properly a subject for next year's report, that the construction of a chamber within which the offensive matters raised by the shred-lifter may be incinerated is being pushed on, and will soon be complete.

LIBRARY OF THE BOMBAY BRANCH OF THE ROYAL ASIATIC SOCIETY

ABSTRACT OF REPORT OF THE HEALTH OFFICER OF BOMBAY FOR 1884.

(D. C. Davidson, Acting Health Officer.)

It is, I think, very desirable that the present state of the building sections of the Municipal Act and the condition of buildings intended for human habitation, which are being daily erected in Bombay, should be prominently brought to notice. The Municipal Act, as it at present exists, is so defective as to afford little or no protection to the public against the erection of most insanitary dwelling-houses, which are directly injurious and dangerous to the health and lives of people, who are compelled by circumstances to occupy them, and are potent factors in bringing about and augmenting epidemics which give rise to much misery and expense, and by causing the imposition of quarantine seriously to interfere with trade. So long as the building sections of the Municipal Act remain as they now are, dwellings of the most unwholesome description—direct causes of disease and pestilence—will from year to year be built with, at all events, the tacit sanction of the municipality. Very large sums of money are being expended on sanitary improvements, and the importance of these improvements it would be difficult to over-estimate; but surely when money is being thus expended for improving the sanitary condition of the city, the minimising of epidemics and reduction of the death-rate, it is not too much to ask that unwholesome buildings, opposed in their construction to the most rudimentary principles of sanitation, factors in the production of epidemics, direct causes, indeed hot-beds of disease, should not only not be reproduced, but erected *de novo* and with impunity. By a large expenditure of money on the one hand certain sanitary advantages are procured, which are, in a measure, counterbalanced by defective legislation on the other.

Plans for almost every description of insanitary buildings are submitted. A not unfrequent form of plan is that for a chawl three or four rooms deep with, perhaps, gullies only three or four feet wide on each side. The centre rooms of such a building have no direct communication with the external air; they are dark, unwholesome dens, into which the light of day never penetrates, and which must of necessity breed disease and pestilence. This is only one instance of the many unwholesome description of buildings being erected in Bombay. Much has been done during the past and previous years in regard to widening roads and streets, and the benefit to the health of the city, which, as a general rule, is the result, is too evident to need comment, and yet it is not unnecessary to inquire whether "set-backs" to improve the line or widen any street are an unmixed good. A man intends to rebuild his house, in the rear of which 10 or 12 feet of open space had been left for ventilation. On submitting plans he is perhaps called upon by the municipality to set back his house 10 feet. What is the consequence? He does not diminish the size of the house and still leave an open breathing space in the rear of 10 feet; he literally sets his house back 10 feet, and builds on the open space which had originally been left for ventilation, thus shutting out light and air from the rear portion of his dwelling, and rendering the back rooms dark, unwholesome dens, into which light and pure air never enter.* It is not only useless, but detrimental to enlarge the breathing space of the streets at the expense of the ventilation of the houses. It is not in the streets that people materially suffer

---

* *Note.*—If this means that because house-ventilation is very insufficiently attended to in the absence of much needed byelaws, therefore street improvement and the provision of additional air-space outside the house should be stopped, and this may be the inference drawn,—I must express my dissent from the Acting Health Officer's opinion. In both respects and in other elementary sanitary requirements improvement must be steadily sought for, but there is no reason in Bombay more than elsewhere that one improvement should be made at the expense of another.—E. C. K. O.

from the effects of imperfect ventilation; it is in their own homes, and anything which interferes with the ventilation of human habitations is in the highest degree detrimental to the public health. The most perfect drainage, the purest water-supply, and the widest streets will not prevent a large amount of disease and a heavy death-rate, especially from affections of the respiratory system, while house sanitation is so woefully neglected as it is in Bombay at the present time. A privy is occasionally built inside a house and overhanging a well; on another occasion a similar structure is built within three feet of a well of drinking water, and a drain is constructed to carry sewage within a foot-and-a-half of the same well; a privy is built or rebuilt underneath inhabited rooms; and yet, notwithstanding the self-evident danger to the public health arising from this, and that such arrangements are opposed to the most rudimentary principles of sanitation, so accustomed have people in Bombay become to them that I have been gravely informed by otherwise fairly intelligent men that such contrivances are "unobjectionable." In such cases it is hopeless to argue and useless to make comments; it is necessary only to state plain facts which any intelligent man ought to be able to comprehend and understand how his own health and life and the health and lives of his fellow-citizens may be sacrificed to a disregard of the first principles of house sanitation.

The question as to the disposal of town sweepings is still under consideration, the refuse in the meantime being deposited on the flats, which proceeding ought to be discontinued, on sanitary grounds, as quickly as possible; but apart from all such considerations, a new method of disposing of the garbage will require to be adopted without delay, as the ground available on the Flats is now nearly filled in, and unless early steps are taken in regard to this important matter, the corporation will find themselves involved in a grave sanitary difficulty. I am still of opinion that the only satisfactory method of disposing of the refuse which can be adopted is to remove it to Coorla, where there is a large tract of waste land belonging to the municipality, practically unlimited in extent for this purpose, which could be reclaimed and would form a valuable estate and from which a large rental could be derived. Instead of trusting to the railway a tramway ought, I think, to be constructed, but this has already been strongly recommended by me in former reports.

In 1883 I drew attention to the condition of milch cattle stables in Bombay in the following terms:—"The nuisance arising from the rapidly growing number of buffalo "stables in Bombay must, sooner or later, force itself upon the notice of the municipality, and they will be called upon to provide a practical remedy. Were places "set apart for this purpose outside the city, and no new stables, save under very "special conditions, licensed in the town itself, the difficulty would in a measure "be solved.

"Complaints are constantly received regarding the nuisance arising from those "places, and I would mention two in particular, where the stables are in a most "insanitary condition, viz., the Downi and those on Mody Bay belonging to the Port "Trust, which during the rains especially are most injurious to the health of the "neighbourhood."

I am glad to be able to report that the milch cattle have, owing to the persistent efforts of this Department, been removed from the Port Trust Property at Mody Bay, but the "Downi" still continues in an insanitary state. The remedy for the unwholesome condition of buffalo stables is entirely in the hands of the corporation. Proper stables ought to be built by the Municipality on some suitable position or positions on the outskirts of the city, and when that has been done, there can be no hesitation in taking rigorous and persistent action against the owners of all insanitary cattle stables in Bombay, and causing them to be vacated. At the present time, when cattle are driven out of any one stable, there is often no other in which they can be accommodated, and they frequently are, under such circumstances, located in quarters much more objectionable than those from which they had been expelled. Again action is taken, and the poor animals are driven elsewhere. No doubt the owners are punished as well as the buffaloes, but no permanent sanitary good is accomplished. The Health Officer is in the position of the London policeman, who has orders to make the street Arabs "move on," but has received no instructions from the municipal authorities as to where they are to go.

Every public milch cattle stable in Bombay should be under the entire control of the municipality, and cleansed, flushed, and kept in proper order by their servants at the expense of the owners. The question of a pure milk supply is of such vast importance to the public health that no effort or expense should be spared to secure it.

The question of some system of medical relief for the poor at their own homes—something similar to the union medical system in England—is one well worthy of consideration. This has been previously brought to notice on several occasions, and, amongst other, by Drs. Weir and Blanc. At the present time the very poor receive no medical relief at their own houses as a part of any recognised system; unless they are able to visit one of the various hospitals or dispensaries, they either die untended or recover as best they may. It is therefore, I think, right, both in the interests of the public health as well as from motives of humanity, that the corporation should organize some system by which the benefit of medical science may be made available in the homes of the poor.

In almost every large town in England, in addition to Union or Poor Law Medical Officers, dispensaries exist, in connection with which medical men are appointed to visit poor patients at their own houses, while the smallest country village possesses a union Medical Officer, and yet this large city of Bombay, with three-quarter of a million of inhabitants, is totally unprovided with any system of home medical relief for the suffering poor.

I would recommend that a medical practitioner be appointed to each ward of the city on a salary of one hundred rupees per mensem, with an allowance for medicines. During epidemics and outbreaks of cholera special medical officers have, during the last two years, been appointed to attend to cholera-stricken people at their own houses. The system was introduced by Dr. Weir, when he was acting as Municipal Commissioner in May 1883, and has worked well, but it will, of course, be understood that it was never intended that this system would enable us to dispense with properly appointed cholera hospitals. The following report was furnished by me at the request of the Town Council in regard to this subject:—

"To THE MUNICIPAL COMMISSIONER.

"SIR,—I have the honour to acknowledge the receipt of your endorsement No. 11,294 of 1884–85, and to state, in reply, that in my opinion the system of appointing special medical officers for cholera duty worked well, and I would recommend that their services should be again solicited in the event of another epidemic of that disease. I do not, however, consider that the treatment of the very poor at their own homes by medical officers at all so satisfactory as would be the treatment of such cases by the same medical men in well-appointed hospitals. There is in many cases an entire absence of that essential of all treatment, viz., good nursing and proper nourishment adapted to the disease and the condition of the patients. Many distressing cases of this description were brought to my notice during the late epidemic, and it was for this and other reasons that I so frequently urged the necessity of providing properly-appointed cholera hospitals within easy reach of cholera-stricken people. If the father and mother are ill, or have died of cholera, there is often no one left to attend upon the sick children, and neighbours and friends not unfrequently decline to hold any communication with them. Under such circumstances, there would be no resource but to remove them to a hospital, when one is available, but if they have to be carried a long distance, as, for instance, from Mahim to Grant Road, this would be impracticable, as, were the patients very ill, they would probably die on the way or shortly after admission. Even in less extreme cases, when a mother has two or more sick children to attend upon, and perhaps the father as well, she cannot devote to them that amount of attention which is necessary to afford them the ordinary chances of recovery, and neighbours are not anxious to render assistance in such cases.

"From the experience I have had I am led to believe that cholera hospitals afford to the cholera-stricken poor by far the best chances of recovery.

"*b.* I think that the measures adopted by the Health Department lessened in a very material degree both the severity and extent of the epidemic.

"*c.* I am not aware of there having occurred any inconvenience to the patients or others from the system adopted. So far as I could observe, the kindness and tact displayed by all the medical officers in dealing with the sick poor precluded any such inconvenience arising."

It is a matter for congratulation that there is now every probability of an increased water-supply being made available, and that some of the initiatory steps have already been taken in regard to the Tansa scheme. As a sanitary officer the want, and the effect of the want, of a proper water-supply are constantly being brought to my notice. An outbreak of cholera rarely occurs, but there is at least suspicion in connexion with the water. This was in 1883 very marked at Mahim and other outlying districts which

are imperfectly supplied. The present intermittent supply is quite insufficient for the wants of the people, and there can be no doubt that it is eked out from wells, the purity of which is often more than doubtful, and the surroundings in many cases of the most insanitary description. If a proper continuous supply were made available, few people would resort to wells, and the result would, I am persuaded, be marked by a decided improvement in the public health. There is no greater sanitary want than this, and no greater benefit could be conferred upon the city than a plentiful supply of pure water.

The registration of deaths in this city is now, and always has been in an unsatisfactory condition. Every effort is made by the health officer to obtain correct information of the causes of death; and regarding cholera, the information obtained, owing to the efforts of the Health Department, is, I think, accurate; but the system which prevails in England, of all medical men furnishing a certificate of the death of those whom they have attended in their last illness, is not adopted here. I am endeavouring to introduce this system. In every case in which the deceased person had been attended by a medical man, the medical attendant will now be asked for a certificate as to the cause of death. Those cases in which a certificate is granted will be entered in the Registrar's returns as "certified," and all others as "uncertified," so that the accuracy or otherwise of our mortuary returns will, in a great measure, in future, depend upon the co-operation of the medical profession of Bombay, and I venture to hope that they will be willing to assist in such a work of public utility and medical interest. As medical advice is more generally sought by all classes, our statistics will prove more and more accurate; and should the proposal, elsewhere recommended, of establishing some system of poor law medical relief be adopted, a great impetus would be given to this important work.*

Vital statistics.

Exclusive of still-born, 22,542 deaths were registered, a mortality 988 less than in the preceding year, but 637 more than the mean of the previous five years. The death-rate, estimating the increase of population, is equal to 27·29 per 1,000 of population. The mortality, as in the previous year, consisted of a low male and high female death-rate; the male mortality was only 25·29 and the female 34·96 per 1,000 of population.

In 1883 the male mortality was 26·62 and the female 36·16 per 1,000 of population. The reduction was, therefore, more than one per 1,000 of population in both sexes since 1883.

Examining the deaths according to places of birth, we observe that 11,106 were born in Bombay, being 318 less than in the previous year, and 11,181 were born elsewhere, and that the place of birth of 255 could not be ascertained.

Examining the population by classes, it will be seen that the proportion of male to female deaths is higher in the immigrating population. The death-rate of females amongst the Jains during the year under report is higher than that of males by 65·2 per 1,000 of population of each sex, and there is reason to believe that it is in a measure owing to the migrating tendency the males of that community possess for trading. On the other hand, in the permanent and non-fluctuating class of population—the Parsees—the death-rate of females as compared with that of males is not so high, being in the proportion of 24·6 to 21·1 per 1,000 of population of sexes.

If we refer to age periods, we find that the fatality of females between 12 and 40 years of age is higher than that of males, and this is, I believe, partly due to diseases and conditions associated with child-birth. The mortality is further enhanced by additional causes, such as employment in cotton mills and wool-cleaning factories, occupations which are injurious to female life.

The rate of mortality from phthisis is higher amongst females than males, and this may be accounted for in a measure by the fact that women of certain castes remain almost entirely, or to a great extent, in their houses without taking exercise in the open air. The more or less vitiated atmosphere which they thus constantly inhale would prove a potent factor in the production of phthisis, more especially when the ill-ventilated condition of a large number of human habitations in Bombay is taken into consideration. In other castes the impure air too often breathed in factories of various descriptions, where large numbers of women are employed, would, to a certain extent, account for the relative higher mortality.

* The section of the Municipal Act relating to this matter is, for all practical purposes, null and void, there being no penalty for non-compliance.—*D. C. D.*

The mortality, arranged according to groups of important death causes, is shown in the table below. There is a reduction in the mortality from small-pox, cholera, phthisis, nervous system, diarrhœa, and dysentery against last year.

Causes of Death.	Number of Deaths.	Rate per 1,000 of Population.	Remarks.
Small-pox	112	·13	Annual increment of population is calculated.
Measles	456	·55	
Fever	6,830	8·27	
Cholera	576	·70	
Phthisis	3,091	3·74	
Diseases of nervous system	2,422	2·93	
Do. respiratory do.	3,744	4·53	
Diarrhœa	1,084	1·31	
Dysentery	635	·77	
Accidents	328	·40	
All other causes except still-born	3,267	3·96	
Total	22,542	27·29	

The infant mortality under five years of age is less than the previous year by 337 deaths. 6,393 children under one year of age died against 6,581. The percentage of deaths in 1884 under one year to total deaths was 28·36, and to that of births registered was 43·67.

Kamathipura still maintains its high rate of mortality amongst children as well as adults. This year it presents a higher death-rate amongst children than any other section of the city with the exception of 1st Nagpada. It will be remembered that it is in the Kamathipura section that house connections have been tried, but I think sufficient time has not yet elapsed for an opinion to be expressed whether the new system of connexions will have any decided effect upon the health and death-rate of the locality.

The lowest mortality is observed amongst Europeans (19·23), but the remark made on this point in the last annual report applies equally to the year under review.* The European mortality is less than the Parsee mortality by 3·63 per 1,000 of population. The Eurasian mortality (37·67) has this year fallen by 12·84 per 1,000 of population, the death-rate in 1883 being 50·51.

Small-pox. The mortality from small-pox has fallen to 112 against 1,461 in 1883, and 343 less than the mean of the previous five years. This is the smallest number of deaths, with the exception of 1881 and 1882, in any one year registered since 1849. The highest mortality was registered in Dhobie Talao ·45, Worlee ·40, and Kamathipura ·35 per 1,000 of population.

Measles. From measles 456 deaths were reported during the year; this shows an increase of 137 deaths over last year. During the first and second quarters of the year 338 deaths were registered. In 1st Nagpada, Upper Colaba and Dongri the death-rate was higher.

Cholera. From cholera 734 cases were reported during the year, of which 576 proved fatal; the death-rate was therefore equal to 0·70 per 1,000 of population. Of the total number of cases 97 persons were born in Bombay, and 637 outside of Bombay; of the cases born in Bombay 81 died, and of those born elsewhere 495 died.

Of the cases reported to have suffered from cholera 569 used Vehar or Tulsi, 89 well water, and in 76 cases it could not be ascertained which water was consumed.

* Examining the mortality according to classes, we find that, of the principal races occupying this city, the lowest mortality is registered amongst Europeans, but this is, no doubt, largely due to the fact that sick Europeans, when practicable, leave Bombay as quickly as possible and die or recover in England or elsewhere, thus reducing the mortality far below what it would be were they placed under the same conditions as other communities.—*Health Officer's Annual Report for* 1883-84.

	Attacked.	Died.
Vehar and Tulsi water drinkers	569	444
Well water drinkers	89	71
Not known	76	61
Total	734	576

The mortality from cholera is 451 less than in the last year, and 152 more than the mean of the preceding five years.

Examining the distribution of the mortality from cholera over the city by sections, we observe that in two sections no deaths from cholera were registered, viz., Upper Colaba and Southern Fort. The highest mortality was registered in Chaupati (2·09), Girgam (1·97), Esplanade (1·91), Mahim (1·79), Dhobi Talao (1·67), and Fanaswadi (1·11).

According to classes the highest death-rate from cholera was amongst the Native Christians (2·24).

Fevers. The deaths from fevers were 6,830 in 1884, 927 more than the last year and 80 more than the average of the preceding five years; 5,307 deaths were referred to remittent fever, being 868 more than the last year; 1,223 to simple continued fever, 282 to ague, and 18 to enteric fever. The highest mortality was observed in Sewri (16·20) and Parell (14·70) sections. In Sewri a greater number of deaths from fever was registered in September, October, and November than the other months of the year.

Other diseases. 3,091 deaths were referred to phthisis, 53 less than in 1883, and 338 more than the mean of the preceding five years. The death-rate from phthisis is higher in Chukla and 2nd Nagpada than the last year. Contrasted with 1883 we observe a diminution in the mortality from phthisis in Khara Talao, a district of a high phthisical mortality, registered in the preceding years, and it now occupies a third place of high mortality. In Chukla, 2nd Nagpada, Khara Talao, Bhuleshwar, Kamathipura, and Oomerkhadi the ventilation of houses is in a large number of cases very defective, and unfortunately not only does this apply to dwellings which have existed for years, but also to many new buildings. I have elsewhere alluded to the absolute necessity there is, in the interests of the public health, of amending the building sections of the Municipal Act. It is universally acknowledged that defective ventilation is a potent cause of consumption, and unless we are enabled to deal with house sanitation in a more effectual manner than at present, I fear there is little hope of reducing the death-rate from phthisis. This question is second to none in the important bearing it has upon the public health, and I consider it my duty to avail myself of every opportunity of bringing it to notice, and earnestly urging that something may be done to remedy the crying evils which at present exist.

Examining the mortality from all causes, there is an increase of death-rate over 1883, principally in 1st Nagpada by 3·52, in Chukla by 3·26, Sewri 2·88, and Mahalaxmi 2·57 per 1,000 of population.

To diseases of the respiratory system 3,744 deaths were referred, being 350 more than the last year, and 835 more than the average of the previous five years; 2,186 were ascribed to bronchitis, being 358 more than the last year and 586 more than the mean of the past five years; to pneumonia 1,188 were referred, 29 more than the last year and 175 more than the average of the past five years.

From diseases of the digestive system 2,288 deaths were registered, being 83 less than the last year, but 243 more than the mean of the previous five years; 1,021, being 79 less than the last year and four less than the average of the previous five years, were referred to diarrhœa; and 635, being 11 less than the past year and 222 less than the mean of the preceding five years, to dysentery; to all other diseases of the digestive system 572 deaths were ascribed, being 7 more than the last year and 17 less than the average of the past five years.

From diseases of the nervous system 2,422 deaths were registered against 2,849 of the last year; 1,980 deaths were referred to infantile convulsions.

Births. During the year 14,637 living births and 1,479 still-born were registered, being 545 less than the last year; 7,634 of the children born living were males and 7,003 females. The proportion of male to female births was 109 to 100. The birth-rate is equal to

17·72 per 1,000 of population. This year the birth registration in certain castes has improved. For instance, amongst Jews the birth-rate has risen from 29·50 to 29·81, and of the Europeans from 17·51 to 17·79; 8 births were registered amongst the Negro Africans against 2 in the previous year.

The system of birth registration is one requiring attention and reform. It is at present in an unsatisfactory state. The principal information is obtained from peons sent round to the different houses by this Department. These peons, or Registration Karkuns as they are termed, are under the general supervision of the Ward Inspectors, who have not sufficient time to devote to this portion of their duties. I think it is, therefore, very desirable that a special officer should be appointed to superintend the Karkuns on, say, a salary of 50 or 60 rupees per mensem. It will also be necessary to enforce the sections of the Municipal Act by which parents and guardians are required to give information to the Registrars of the districts in which they live.

APPENDIX.

No. 1.

MEMORANDUM of the ARMY SANITARY COMMISSION on the REPORT of the SANITARY COMMISSIONER with the GOVERNMENT of INDIA for 1884.

1. In our Memorandum on the Sanitary Commissioner's Report of last year, we noticed the fact that it was the twentieth and last of the annual Reports of Dr. Cuningham, who for that long term had filled the office of Sanitary Commissioner with the Government of India, much to the advantage of sanitary improvement. The present Report has been prepared by his successor, Surgeon-General Dr. B. Simpson, and as the same arrangement of subjects and material has been followed in the present as in preceding Reports, we shall proceed to discuss its contents in the usual order.

2. The following table gives an abstract of the inefficiency statistics for the whole European Army in India since the year 1870:—

Years.	Strength.	Ratios per 1,000 Strength.				
		Admissions.	Daily Sick.	Deaths.	Invalids.	Total Loss.
1870-79	527,416	1,475	60	19·84	48	62
1878	56,475	1,651	68	21·46	45	66
1879*	49,582	1,977	78	24·28	49‡	73‡
1880*	51,796	1,789	74	24·35	25‡	51‡
1881†	58,728	1,605	70	16·86	38	55
1882	57,269	1,445	65	12·07	33‡	45
1883	55,525	1,336	63	10·88	33	44
1884	54,996	1,513	67	13·56	32	44

* Excluding troops serving in Afghanistan. † Including troops in Afghanistan.
‡ Calculated on the strength obtained from annual returns.

3. It will be seen from this table that the year 1883 presented as a whole the most favourable aspect of Army health in India; and in our remarks on the data we pointed out the necessity of securing the improvement in health which had been attained, and that an outbreak of epidemic disease would easily alter the data. It hence follows that one of the problems presented by these statistics is the reason why the ratios of admissions, daily sick, and deaths have increased, and to arrive at this information we must first ascertain where the increase in these inefficiency rates has taken place, and, if possible, what has been the cause. A reference to the table shows that the increases of 1884 have been in the admissions, daily sick, and death-rates, and we shall next show to what extent these took place in each of the European Presidency Armies.

4. The data for the Bengal Army were as follows:—

	Ratios per 1,000 Strength.		
	Admissions.	Daily Sick.	Deaths.
1883	1,463	66	11·21
1884	1,682	70	11·68
Increase in 1884	219	4	·47

The increase of 0·47 in the death-rate in the Bengal Army was mainly due to 0·40 from cholera over the cholera-rate of 1883.

5. The corresponding data for the Madras European Army stood as follows:—

	Ratios per 1,000 Strength.		
	Admissions.	Daily Sick.	Deaths.
1883	1,013	59	10·19
1884	1,109	57	8·53
Plus and minus 1884	+ 96	− 2	− 1·66

It is clear that the Madras Army added only 96 per 1,000 to the admissions, while its daily sick and death rates were under those of the preceding year. The cholera death-rate in this Army, which was 0·95 in 1883, was 0·93 in 1884.

6. The Bombay Army yielded the following ratios:—

	Ratios per 1,000 Strength.		
	Admissions.	Daily Sick.	Deaths.
1883	1,249	57	10·50
1884	1,455	65	19·39
Increase in 1884	206	8	8·89

Of the increased death-rate, 4·03 was due to cholera, which in 1883 showed a ratio of 0·82 and in 1884 one of 4·85 per 1,000.

It is evident from these data that the causes of increased mortality and inefficiency are to be sought mainly in the Bombay Army, and that it will be necessary to deal with these separately before the real death-rate for the whole European Indian Army comparable with the rate of 1883 can be arrived at.

7. For this purpose we shall abstract the facts given in Dr. Stephen's tables at the end of the Report under review, and as the question at issue relates to the sanitary condition and improvement of Bombay stations, we shall deal with the station death-rates.

At 19 stations in Bombay, including Deolali depot, there was an average strength in 1884 of 8,932 men, among whom there 98 deaths, or 10·97 per 1,000. But there were other two bodies of men, of whom 1,079 were at Quetta, in Southern Afghanistan, and 1,088 were marching in the same country. At Quetta there were 41 deaths in 1884, or a ratio of 38 per 1,000. Among the marching troops there were in four months 58 deaths, or 53·31 per 1,000. By adding these data, the death-rate is raised for the whole Bombay Army to 13·44 per 1,000, and with a few deaths among troops on the march in Bombay Presidency, we arrive at the whole year's increase.

8. It is quite true, statistically, that the Bombay Army shows a considerable increase of mortality in 1884. But when dealing with such questions for practical sanitary purposes, it is necessary to bring the facts home to their proper causes, and the result in the present case is that the sanitary problem in Southern Afghanistan is another thing than it is in Bombay. We have endeavoured in our Memorandum on the Bombay Army Report for 1884 to show wherein this difference lies, and the treatment it requires.

9. Acting on this view of the case, we may deduct the Afghanistan strength and deaths from the Indian aggregate, and we shall have a strength of 52,829 men, yielding 592 deaths, or in the ratio of 11·2 per 1,000, or 0·32 in excess of the rate of 1883. We shall show afterwards the cause of this increase, and we may contrast this estimate with the results for an average strength of 1,441 men in Afghanistan, the annual death-rate among whom, as given by Dr. Stephen, was 68·70 per 1,000.

10. We shall next give the data for each Presidency army separately:—

Army of Bengal.

Period.	Average Strength.	Ratios per 1,000.				
		Admissions.	Daily Sick.	Deaths.	Invalids.	Total Loss.
1870–79	368,431	1,522	61	21·00	41	62
1878	35,536	1,675	68	21·63	40	62
1879*	29,255	2,108	82	29·82	47†	77†
1880*	31,583	1,873	75	27·73	22†	50†
1881*	35,901	1,729	72	17·65	37†	54†
1882	35,164	1,579	69	13·17	35	48
1883	34,972	1,463	66	11·23	31	42
1884	33,486	1,652	70	14·68	32	44

* Excluding troops in Afghanistan. † Including troops in Afghanistan.

The death-rate among Bengal troops was slightly raised in 1884, as were also the other sources of inefficiency. The difference was not great, but quite sufficient to call for watchfulness. The increase in 1884 amounted to 0·47 per 1,000, and of this amount 0·40 was due to a rise in the death-rate from cholera from 0·94 per 1,000 in 1883 to 1·34 in 1884.

11. *Army of Madras* :—

Period.	Average Strength.	Ratio per 1,000.				
		Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
1870–79	10,896	1,264	59	17·69	40	57
1878	10,815	1,392	66	21·82	48	70
1879	10,444	1,428	68	16·56	45	62
1880	10,310	1,366	64	10·18	20	30
1881	10,391	1,160	60	10·97	28	39
1882	10,020	1,058	57	10·25	24	34
1883	10,498	1,013	52	10·19	33	43
1884	10,785	1,109	57	8·53	32	40

The decrease of 1·66 in the death-rate shown by the table was not due to cholera, although there was a slight reduction from 0·95 per 1,000 to 0·93. The reduction took place in other death causes outside cholera, and these yielded a death-rate of 7·60 in 1884 against 9·24 per 1,000 in 1883. On the whole the result was not unsatisfactory.

12. *Army of Bombay* :—

Years.	Average Strength.	Ratios per 1,000.				
		Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
1870–79	103,587	1,533	57	13·27	43	58
1878	9,825	1,848	67	20·46	58	78
1879	9,883	2,173	78	15·78	60	76
1880	9,903	2,150	78	30·90	49	80
1881*	9,895	1,784	72	18·44	53†	67†
1882	11,085	1,485	61	10·37	36	46
1883	19,948	1,249	57	10·50	38	48
1884	10,725	1,455	65	19·39	31	51

* Excluding troops in Afghanistan. † Including troops in Afghanistan.

We have already stated that the death-rate in the Bombay army in 1884, included the rate in Southern Afghanistan, by deducting which the rate for Bombay stations becomes 10·97 per 1,000, showing an increase of 0·47 per 1,000 on the rate of 1883, but otherwise the year's result was likewise not unsatisfactory.

13. We shall next give the death-rates for the same periods for different groups of Bengal stations :—

Periods.	Death-rates per 1,000.						
	Bengal Proper.	Gangetic Provinces and Oudh.	Meerut and Rohilkund.	Agra and Central India.	Punjab.	Hill Stations.	Bengal Presidency.
1860–69	29·57	28·59	26·61	38·48	25·24	14·78	29·98
1870–79*	14·48	20·06	18·31	18·41	20·71	12·23	21·00†
1880*	16·03	22·32	22·98	15·67	36·44	20·75	27·73
1881*	12·02	15·94	17·81	10·11	23·44	9·97	17·05
1882	11·19	22·61	8·86	10·51	12·12	8·65	13·17
1883	9·10	12·04	10·56	14·27	9·47	6·83	12·21
1884	10·07	14·72	17·01	15·58	9·75	5·91	11·68

* Excluding troops in Afghanistan and on the march.
† Including troops in Afghanistan and on the march.

The contrast between the death-rates in the earlier and later years of the series given in these groups is very remarkable. But there is evidence in the inconstancy of the more recent death-ratios to show the need of vigilance in looking after the sanitary condition of the stations, especially those in Meerut and Rohilkund.

14. We have omitted the admission-ratios in the comparisons on account of the large and variable admission-rate from venereal diseases at different stations. It will be sufficient on this subject to state the admission-rate for each of the three armies :—

	Admissions per 1,000 from Venereal Diseases in 1884.
Bengal	281
Madras	307
Bombay	292

15. We shall next give a brief account of the chief causes of inefficiency in the course of the year:—

Diseases.	Ratio per 1,000.							
	Bengal.		Madras.		Bombay.		Army of India.	
	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.	Admissions.	Deaths.
Cholera	2·1	1·34	1·1	0·98	6·3	4·85	2·7	1·95
Small pox	1·5	0·18	1·8	0·09	0·7	0·09	1·4	0·14
Enteric fever	12·6	3·81	11·4	1·67	9·1	2·05	11·7	2·74
Intermittent fever	623·2	—	129·7	—	419·7	0·09	486·8	0·02
Remittent fever	59·6	0·36	36·3	—	84·7	2·05	59·9	0·62
Continued fever								
Apoplexy and sunstroke	3·2	1·04	1·7	0·84	4·0	1·49	3·1	1·09
Delirium tremens, &c.	9·9	0·21	3·8	0·09	9·0	0·09	8·2	0·16
Dysentery	21·6	0·18	55·6	0·37	26·5	1·03	29·2	0·38
Diarrhœa	51·3	0·03	42·4	0·19	53·2	0·18	49·9	0·09
Hepatitis	26·0	0·84	36·2	2·04	18·2	1·03	26·5	1·11
Spleen disease	5·1	0·06	0·5	—	2·6	—	3·7	0·04
Respiratory diseases	79·2	0·72	45·8	0·09	82·1	1·40	73·2	0·78
Heart diseases	—	0·18	—	0·09	—	0·37	—	0·20
Phthisis pulmonalis	7·3	0·93	5·2	0·28	8·1	0·75	7·0	0·76
Rheumatism, &c.	50·8	—	45·7	—	40·3	—	47·9	—
Violent deaths, wounds, &c., accidents, suicides	124·3	1·23	114·0	1·20	114·6	2·24	120·4	1·42

This table shows the ratios of disease admissions and deaths, but it scarcely enables us to form an estimate of the work actually done by the Indian Army medical staff in 1884. There were received into hospital in the course of the year 83,230 patients, of whom 30,787 were suffering from fevers, and 16,166 from venereal diseases, and there were 6,619 wounds and accidents treated.

16. In previous Memoranda we have shown the causes of decreased or increased mortality from the chief diseases during past years, and we shall here continue the data for each army, beginning with cholera:—

	Death-rates per 1,000.		
	Bengal.	Madras.	Bombay.
1860–69	9·24	—	—
1870–79	4·18*	1·68	1·53
1880	4·84†	·10	—
1881	3·23*	1·73	·30
1882	1·26	·82	·63
1883	·94	·95	·82
1884	1·34	·93	4·85

* 24 per cent. of this rate took place in Afghanistan in 1879. † Excluding troops in Afghanistan.

There has been a great reduction in cholera death-rates since 1860, especially in Bengal; but as already has been stated, the great increase in the Bombay Army in 1884 was due, not to Bombay, but to Southern Afghanistan, where out of a total loss from cholera by 52 deaths 39 took place, leaving 13 deaths for the Bombay stations.

17. A further analysis of the data for Bengal Presidency will enable us to trace more clearly the places where reductions in cholera mortality have taken place, as follows:—

Periods.	Deaths from Cholera per 1,000.					
	Bengal.	Gangetic Provinces.	Meerut and Rohilkund.	Agra and Central India.	Punjab.	Hill Stations.
1860–69	6·26	8·12	6·55	15·94	6·39	1·80
1870–79	·85	4·24	2·06	3·22	3·95	1·60
1884	1·06	3·17	4·19	1·75	—	—

This abstract shows a great reduction of losses from cholera since 1860, but it contains warnings also against relaxation of efforts to root out the local predisposing causes of this disease. Moreover, the deaths registered from cholera in 1884 among the civil population in the same divisions were fewer than those among troops in proportion to their numbers, but the registration cannot altogether be relied on in such comparisons. All that can be said is that there was a severe epidemic of cholera over the north of India, and that in certain divisions it showed a tendency to increase at the stations,

showing that greater activity in dealing with its local predisposing causes is required. Of the stations, Meerut was the chief offender, and yielded 28 cases of cholera, of which 13 proved fatal.

18. Cholera, besides being a disease attacking localities, is also an epidemic, but the chief death cause was not cholera, but enteric fever, which is a more purely local disease than cholera.

The whole Indian Army, including troops in Southern Afghanistan, yielded 167 cholera deaths, but the same troops yielded 151 deaths from enteric fever, and there is no doubt that, statistically, the deaths from enteric fever have been increasing, as this abstract appears to show:—

	1870-79. Deaths per 1,000.			1884. Deaths per 1,000.		
	Enteric Fever.	Other Fevers.	Total.	Enteric Fever.	Other Fevers.	Total.
Army of India	2·08	1·42	3·45	2·74	·64	3·38
„ Bengal	2·28	1·74	4·02	3·31	·36	3·67
„ Madras	1·42	·62	2·04	1·67	—	1·67
„ Bombay	1·75	1·14	2·89	2·05	2·14	4·19

We have discussed this subject year after year, from the time that the very name of enteric fever did not appear in the statistics. We have shown how and when it first appeared, and the fever types from which enteric fever had been taken. The question at present, however, is not if there be such a disease in India, but whether, as shown by the figures, it is increasing. Instead of resuming the discussion, we shall simply quote the remarks of the Sanitary Commissioner in the present Report, which have an important bearing on the subject.

Referring to the preceding abstract, he says:—"The question as to whether all the fevers now so "often called enteric are really specifically distinct from malarial fevers, and whether, if these be so, "these fevers are specifically the same as the fevers similarly named in Europe, will have to be decided "on clinical and pathological data. As far as the indications of statistics may be relied on, they tend "to show only that, if the fevers now called enteric are really specifically distinct from malarial "fevers, they have always been so, though they have escaped observation, and are probably not to be "regarded as a newly introduced disease into India. It was, indeed, to be expected that a more careful "observation of fevers, stimulated by the introduction of improved and accessible instruments of "research, should result in the separation of some of their forms as distinct which were formerly "regarded as the same. This view is supported by the results set forth in the above tables, which "show that the total mortality from all forms of fever does not, on the whole, materially differ from "what it was 13 years ago, and this is hardly compatible with the view that a new and fatal fever "has been recently introduced into India."

19. *Post mortem* examinations may be assumed as having settled the diagnosis in the 151 fatal cases. But there were 644 cases of enteric fever admitted throughout the Army, and the diagnostic difficulty occurs not with the fatal cases, but with the admissions, while, so far as we can judge, there are considerable diversities of opinion as to what group of symptoms constitute a case as one of enteric fever. But so far as our own work is concerned, we should have no objections to assume all the cases as marking severe types of fever, requiring special local discussion and inquiry with the view of determining and dealing with their removable causes.

20. That there are local reasons of some kind or another to be dealt with scarcely admits of a doubt, even from the evidence furnished by statistics. For example, as we shall presently see, the amount and fatality of enteric fever depends on two numerical factors; 1st, the annual proportion of men under 25 years of age in the Indian European Army; 2nd, the proportion of these young men who have served for two years or under in the country. But it is at this point we find the question of locality presents itself, for on turning, for instance, to Dr. Stephen's tables, we find that at Agra and the six Central India stations, where there were 3,933 men, there were 64 enteric fever admissions, 30 of which proved fatal, and yielded a death-rate of 7·51 per 1,000 for the command. Of the cases 22 and 7 deaths took place at Agra, and 33 cases and 17 deaths at Morar.

We have already alluded to the comparatively new station of Quetta, in Southern Afghanistan, where 1,079 troops at the station and 1,088 in the Zhob expedition and on the march yielded, the former 32 enteric fever cases and 10 deaths, and the latter 3 cases and 1 death. This Afghanistan outbreak yielded an annual death-rate of 7·63 per 1,000, not far from the Central Indian rate.

Now, by way of contrast, let us take the Punjab stations, where 10,874 men yielded an enteric fever death-rate of 2·30 per 1,000, and the hill stations and sanitaria, where the enteric fever death-rate was 1·03 and 1·71 per 1,000, or the Madras stations, where the rate was 1·04 per 1,000.

21. If we are to assume young ages, short service, and climate as the determining causes of these various rates, are we in possession of facts to show that the proportion of men fulfilling these conditions varied so greatly in the different Army commands as to account for the facts of relative mortality? Of course, the reply is in the negative, so that without being obliged to deny that a young soldier may be struck with enteric fever immediately on his landing in India, we are compelled to seek for the causes of varying liability in the localities themselves, and it is here that the sanitary service has to be put under requisition to discover and remove the causes. After a man is in hospital, the insanitary conditions which sent him there have done their work. The distinction is an

important one, for it carries back the disease history to a period of days or even weeks before the patient came under medical care.

22. One chief use of the immense amount of sanitary statistical information which has been collected from every station in India, has been to enable the sanitary officer to lay his hand at once on local disease causes, and we must refer to the past annual figures for the stational information he requires. With that before him, he will have no difficulty in connecting enteric fever with general epidemic and local conditions, which lie at the root of other diseases of the class, for they are all of the same descent, although differing in external characters. There ought to be no great difficulty in dealing with the causes, if an attempt be made to realise what they are. And on this aspect of the question there is amply sufficient experience to guide us. Enteric fever has taken it victims from among all ranks of society, and from the inhabitants of palaces as well as from among the tenants of hovels. Its apparent impartiality in this respect has sometimes led to doubts of its relation to local conditions. But case after case has, on inquiry by skilful hands, led to a tolerably general conviction that in this, as in other instances of experience, there must be a cause preceding the effect; but we must avoid falling into the error that the complicated relations of what are called "disease causes" to the living healthy organism partake of the nature of ordinary chemical or mechanical agencies acting on dead matter.

23. A case of fever may be the final result of a failure of resistances against morbid agencies, as well as of the direct influence of the morbific agent. Take, for example, cases which have actually happened. A family inhabits a house, to the insanitary conditions of which its members have become more or less accustomed. A visitor arrives, and is attacked by fever, while the family escapes. Another family has occupied a house with apparent immunity until an accidental indraught of sewer air has lighted up fever. At the time a large mansion was built on clean gravel and on a healthy site, the great importance of isolating the rooms from any chance of air connexion with the subsoil was not recognised. Being lived on, the subsoil became in time unhealthy, and long years afterwards enteric fever entered the building.

A more common class of cases includes those in which whole streets of costly houses were erected without drainage. The house sewage was passed into cesspits to pollute the subsoil. In time the houses are drained, and the cesspits forgotten, until under certain changes of atmosphere enteric fever appears.

Take a late Indian case. The occupant of a ground floor bedroom was seized with fever, and had to undergo a long convalescence at a distance. Another occupant had a bed placed on the same spot, and was seized with enteric fever and died. The flooring was then removed, and the earth dug up. It smelt so bad that people were obliged to go away. This, which in all probability is a common Indian case, was caused by the infiltration of used bath water into the subsoil of the bedroom.

In India enteric fever has been assigned by medical officers who saw the cases to foul emanations from latrines, and to imperfect methods of dealing with latrine matter. Again, there is a whole class of cases in which enteric fever has appeared among troops camped on old used up ground, both in the East and West. Evidence taken before the Royal Commission of 1859 showed that an Indian cantonment is simply a town without drainage, and half a century ago Dr. Southwood Smith showed that wherever the Commissioners of Sewers in London had not been, there was fever.

24. Suppose, then, that a camp or barrack site has been used for a number of years, and the ground left to itself without drainage to enable the rainfall to wash out the subsoil; suppose, moreover, that no provision has been made for turning the roof water away from the foundations, and that in times past there have been cesspits and middens in use instead of cleansing, and that the barrack room air is in communication with the subsoil air to which the usual lavatory water has access. Is it not rather a matter of surprise that there are so few fatal cases at fever stations so managed?

25. All these are merely commonplaces of every day sanitary experience, and no doubt they could be added to by the experience of most Indian stations. There are instances in which these fevers have apparently been connected with the use of bad water. But, taking the facts as a whole, it will be found that the evil is generally in the subsoil, and it is there it has to be dealt with. But there are cases in which the fever cause may have been brought by air currents from a distance, so as to reach men in upper floor rooms more readily than those on the ground floor, thereby discrediting upper floors. These, however, are exceptional, and there are cases which are traceable to the topographical relations of the subsoil, by which water may be retained in underground pits and hollows not visible on the surface.

26. The object of these remarks is to show in what direction local inquiries at the enteric fever stations enumerated in Dr. Stephen's statistics ought to be carried out, and we need only add that it is time this work was undertaken. Mere surface appearances cannot be trusted to any longer. So far as these are concerned, the Sanitary Commissioner informs us that medical officers state that "no clue "whatever can be found to the causation of the disease in any local unsanitary conditions." Should this view be finally established, the practical result would apparently be to confirm the opinions of those officers who consider enteric fever as being a condition or stage of Indian fevers, and as these fevers are the products of malaria and climatic causes, we should have to deal with these general agencies instead of with local causes, such as are elsewhere connected with this fatal disease. But until the subsoil conditions existing at old stations and the relation of these to the barrack atmosphere have been worked out, it would scarcely be justifiable to conclude that causes of a local nature have nothing to do with a fever which is now the chief death cause in the European Army of India.

27. As we have discussed this subject at length in other papers with special reference to the relation of enteric fever to other Indian fevers, it is unnecessary to do more than merely to state,

that if the view held by some medical officers as to the identity of all these fevers were adopted, it would in no way change the character of the sanitary works and measures required at the stations, but it would necessitate the extension of them beyond the station limits, so as to include outside sources of malaria. It will, however, be quite time enough to deal with this aspect of the question when the stations have undergone thorough drainage and cleansing of their own subsoils, and when the men's rooms have had their ventilation cut off from that of the subsoil.

28. The next abstract gives the death-rates for a series of years from dysentery and hepatitis:—

Periods.	Death Ratios per 1,000.							
	Army of Bengal.		Army of Madras.		Army of Bombay.		Army of India.	
	Dysentery.	Hepatitis.	Dysentery.	Hepatitis.	Dysentery.	Hepatitis.	Dysentery.	Hepatitis.
1860–69	2·72	3·31	—	—	—	—	—	—
1870–79*	1·37	2·06	2·32	3·16	·98	1·71	1·48	2·19
1880	2·72†	1·36†	·58	1·26	4·14	1·37	2·96	1·33
1881†	1·00	1·64	1·15	1·54	1·82	1·52	1·72*	1·60*
1882	·77	1·48	·36	1·72	·18	·81	·57	1·40
1883	·35	1·06	·28	1·72	·55	·82	·38	1·18
1884	·18	·84	·37	2·04	1·03	1·03	·38	1·11

* Including troops on active service and on the march. † Excluding troops in Afghanistan.

It is satisfactory to observe that there has been a constant decrease in mortality from dysentery and hepatitis for the Indian Army as a whole. The decrease has been most marked in the Bengal Army. But in the Army of Madras there has been an increased mortality under both heads. Why the Madras rates should be so much higher than those of the other Armies has not yet been explained.

The best prophylactics against both diseases are temperate habits, including abstinence from spirituous drinks, flannel next the skin, managing the night ventilation so that air draughts are kept from falling on the men at night, and attention to clothing, to meet varied changes of temperature.

29. Admissions and deaths from sunstroke and apoplexy are nearly a constant quantity. In 1884 the admissions were 3 per 1,000 and the deaths 1·09 per 1,000. It is to be feared that some part of this loss is due to drink as well as to climatic causes.

30. Respiratory diseases are not subject to much variation in the Indian Army as a whole. In 1884 the admissions under this head were 73 per 1,000, of which just a tenth part, or 0·73 per 1,000, proved fatal. There was a considerable increase, however, in the Bombay Army due to the cold variable climate of Quetta, where part of the troops were stationed.

31. We have already referred to the unsatisfactory state of Army health from the amount of venereal diseases, which show a tendency to increase rather than to diminution. The earliest records show that during the ten years, 1860—69, the Bengal Army had a venereal admission-rate of 265 per 1,000, which in 1884 had risen to 291 per 1,000. The earliest accounts for the whole Indian army are those for the ten years, 1870—79, which gave a rate of 203 per 1,000, while the rate of 1884 was 294 per 1,000. The greatest increase, however, has been in the Madras Army, which has risen from an average of 198 per 1,000 in the ten years, 1870—79, to no less than 397 per 1,000 in 1884. Active police and lock hospital precautions have been in force everywhere, and special attention was drawn by us formerly to the apparent success of these measures in Bombay. But the statistics show that, including the periods before and since the precautions were introduced, the syphilitic rate has risen from a ten years' average, 1870—79, of 191 per 1,000 to 292 per 1,000 in 1884.

The whole subject appears to be surrounded with insurmountable difficulties, for in every Government the disease has advanced in the face of every means of prevention which have been adopted.

Some individual stations present extraordinary results. Madras, for example, is supposed to have an efficient police and lock hospital system, and yet in 1884 its venereal admissions were 485·3 per 1,000, Belgaum of 377·8 per 1,000, and Calicut of 390·1 per 1,000, but in this case there were under 100 troops.

32. *Invaliding.*—The following table gives the invaliding statistics for the year 1884:—

Armies.	Number invalided.	Invalided per 1,000 Strength.
Bengal	1,074	31·84
Madras	343	31·32
Bombay	340	31·36
India	1,757	31·74

Of the number invalided 1,035 were sent away for change and 722 for discharge. The chief invaliding cause was "debility," on account of which 266 men were sent home. There were 159 invalids from hepatitis. These two causes included about a fourth part of the invalids out of 106 assigned causes.

The invaliding rate was lower in 1884 than in any previous year, with one exception, and the figures given above show that it was nearly the same in all the Armies.

33. To recapitulate:—As has been already shown, there has been an apparent rise in the death-rate of the European Army as a whole, from 10·88 to 12·56 per 1,000, due to a considerable increase in the Bombay Army rate of 8·89 per 1,000. But this rate in its turn can be traced almost entirely to that part of the Bombay Army on service in Southern Afghanistan. The real rate due to the Bombay stations was 11·2 per 1,000 and the Afghanistan rate and its causes is a separate problem. Making allowance for this, we have shown that the death-rate of the European Indian Army, as a whole, was 11·2 per 1,000, or ·32 per 1,000 above the rate of 1883, which was 10·88 per 1,000, the lowest on record. The slight increase was mainly due to cholera in Meerut and Rohilkund, and shows the need of more active precautionary measures at these stations. This is the lesson taught by another year's experience, which, however, on the whole, and with the exception of the Afghanistan results, cannot be said to be unsatisfactory. The practical teaching of the year's facts for the whole Army is that every effort should be made to discover and root out the causes of enteric fever at the 45 stations which yielded deaths from this disease in 1884. That there are local causes for this mortality cannot admit of a doubt, although the necessarily surface observations of medical officers may have failed hitherto to discover them. And as these causes are dealt with we may rest assured that cholera, as well as enteric fever, will be less apt to enter, for there is every probability that the two diseases are localised by similar causes.

34. In former memoranda we have called attention to the apparently greater liability to death of newly arrived regiments, and as the experience of 1884 is exceptional in this matter, it is necessary to state it. The admission rate for the Army generally was 1513·4, the daily sick rate 67 per 1,000, and the death-rate 12·56 per 1,000. The corresponding ratios for newly arrived regiments were as follows:—

	Per 1,000.
Admissions	1341·6
Daily sick	62·2
Deaths	10·88

But the most important difference was in the enteric fever death-rate, which for the Army generally was 2·74 and for new regiments 2·33 per 1,000.

35. *European women and children.*—The death-rate among women was 17·50 per 1,000, the lowest on record. Ten years earlier, in 1875, the rate was 25·89 per 1,000. During the same year the children's death-rate was 69·75 per 1,000. In 1884 it was 54·86 per 1,000, but the children's rate is subject to greater variation than the rate for adults.

36. *Officers.*—The following abstract shows the death-ratios among officers:—

	Strength.	Deaths.	Ratio per 1,000.
British	2,773	29	10·7
Indian	2,929	25	8·5

Of the 54 deaths, 6 were due to enteric fever, 5 to cholera, and 5 to apoplexy. There were six deaths among the absent, and one death at sea.

37. Considered from the practical side, these statistics of the European Army as a whole show continuous improvement in the sanitary state of the Army, and that of late years much good has been done, and we shall next see that the health of the Native Army has undergone even greater relative improvement, although it has not as yet arrived at the same sanitary standard as that presented by the European Army.

38. *Native Army.*—Instead of abstracting full statistical details under this head, it will be sufficient to compare the earliest and latest years of the series, which stand as follow for the Native Army as a whole. For the years 1877 to 1881 the average inefficiency rates were:—

Admissions per 1,000	1,422
Daily sick ,,	48
Deaths, including absent deaths	27·40

The same data for 1884 were:—

Admissions per 1,000	1,042
Daily sick	33
Deaths, including absent deaths	12·22

Excluding absent deaths, the rate was 10·50 per 1,000, but as the European death-rate includes all deaths under its ratio of 11·2 per 1,000, after the corrections required for Quetta, it is this rate

which should be compared with the total Native Army rate, 12·22 per 1,000. The improvements in both rates have hence been very great, while they hold out expectations of still further reductions and increase of efficiency.

39. The next abstract shows the inefficiency rates per 1,000 for each of the Native Armies in 1884.

Armies.	Strength.	Ratios per 1,000 Strength.		
		Admissions.	Daily Sick.	Mortality, including absent Deaths.
Bengal	40,850	1,193	35	12·56
Madras	28,050	836	31	11·82
Bombay	23,373	1,159	38	14·35
Punjab Frontier Force	16,458	1,262	35	14·00
Central Indian Regiments	5,082	644	20	7·23
Hyderabad Contingent	7,014	574	19	5·30

40. The chief admission causes in the Native Army were fevers of the intermittent type, from which the admission-rate was 490·0 per 1,000, slightly above the rate for European troops, which was 486·9 per 1,000. Remittent and continued fevers yielded 12·3 per 1,000 in the Native Army, against 59·9 per 1,000 in the European Army. Dysentery yielded 48·7 admissions in the Native Army, against 29·2 in the European Army.

The chief death causes in the Native Army were respiratory diseases, from which there were 341 deaths, or 2·97 per 1,000. To this group was due 25 per cent. of the year's mortality, a fact which suggests inquiry regarding clothing and shelter, whether both are suited to the diverse climates where the Native Army serves.

There were 82 deaths from cholera, equal to 0·71 per 1,000, and 10 deaths from small-pox. The fevers proper gave rise to 207 deaths, or 1·80 per 1,000. Eleven of these deaths were attributed to enteric fever, 52 to intermittent, and 144 to remittent and continued fevers.

41. The death-rates of the Native Army were made up of various ratios, but some were so high as apparently to call for inquiry as to the sanitary condition of the stations.

Dhuki and Gumbuz yielded a death-rate of 68·35 per 1,000, Dibrugarh of 25·7 per 1,000, Dehra Dun of 25·27 per 1,000, Alipore and Baliganj of 24·24 per 1,000. It is not at all unlikely that skilled sanitary inquiry would find some reason for these rates. So far as can be estimated from the tabular statement of Native station returns, there are many disease causes connected with the lines and hutting which require attention.

42. *Jails.*—Section IV., which is devoted to an account of statistics and sanitary condition of jails all over India, contains much useful information regarding 252 of these establishments. Of late years much good work appears to have been done in many of them, and the following abstract shows that the health of prisoners has improved:—

Periods.	Average Strength.	Ratios per 1,000.		
		Admissions.	Daily Sick.	Deaths.
1872–76	99,758	1,016	?	36·24
1877–81	112,670	1,189	44·9	63·01
1880	106,763	1,213	46·	48·31
1881	100,344	1,214	45·	44·03
1882	94,063	1,214	42·	39·96
1883	88,174	996	36·	34·37
1884	85,496	1,025	37·	29·11

During the years shown in this table there has been a great and continuous reduction in the death-rates, and this improvement has co-existed with reduction in the prison population, which means less crowding and more ventilation.

43. The data for the jails of each Presidency for the year 1884 have been as follows:—

Presidencies.	Average Strength.	Ratios per 1,000.		
		Admissions.	Daily Sick.	Deaths.
Bengal	51,877	1,028	34	32·71
Madras	6,959	765	29	30·55
Bombay	7,305	702	26	34·91

The largest amount of sickness is thus shown to have prevailed in the Bengal jails, the highest death-rate in the Bombay jails, and the lowest in Madras jails.

44. We shall next compare the admission and death-rates from the chief diseases during 1884 with those of the previous ten years:—

Diseases.	Ratios per 1,000.			
	Admissions, 1873-82.	Deaths, 1873-82.	Admissions, 1884.	Deaths, 1884.
Dysentery and diarrhœa	175	13·90	223	12·66
Respiratory diseases	44	7·16	36	6·03
Fevers	488	5·29	452	2·16
Cholera	?	3·46	2·9	1·52
Atrophy and anæmia	28	3·10	28	2·10
Phthisis pulmonalis	?	·50	5·7	2·12
Dropsy	?	·80	3·6	·85
Wounds and accidents	41	·68	35	·46
Spleen diseases	?	·35	5·9	·27
Apoplexy	?	·66	·4	·52

We have no means of completing the admission column for the ten years, but the death columns show a remarkable reduction in this datum for all the chief prison diseases.

45. Like many other averages, however, these general data are deceptive, for they are made up of maxima and minima; but as the statistics of each jail are given in the Report, we may obtain a more accurate idea of the jail mortality by arranging the data so as to show the number of jails in which specified death-rates prevailed in 1884:—

Death-rates per 1,000 average Strength.	Number of Jails in which the Rates existed.
Under 10	19
10 to 20	57
20 to 30	46
30 to 40	24
40 to 50	21
50 to 60	14
60 to 70	8
70 to 80	6
80 to 90	2
100 to 110	6
120 to 130	2
140 to 150	1
150 to 160	2
256·52	1
Total	209

It is quite certain from these figures that the death-rates in many jails are excessive, but in 1884 part of the high rates was due to cholera, which appeared in 32 of them at a time when it was epidemic in the districts within which the jails are situated. But the other jails, which were also in cholera districts, escaped. Thus Julpaiguri jail, which had a death-rate of 155·96 per 1,000, had no cholera. Mymensingh jail, with a death-rate of 148·88 per 1,000, had only three cholera deaths. And Rungpore jail, which yielded the highest death-rate of the year, namely, 256·52 per 1,000, had no cholera. The preceding abstracts show that, out of an average death-rate of 29·11 per 1,000, the cholera-rate was 1·52 per 1,000, somewhat in excess of 1·43 per 1,000 which ruled all over India. But the cholera death-rate in certain jails greatly exceeded this average. In Gya the death-rate from cholera was 24·26 per 1,000. In Monghyr it was 36·08 per 1,000, and in Akyab jail it was 52·63 per 1,000. No doubt the importance of the figures is lessened by the comparative smallness of the jail population in several of the 32 jails where the disease appeared. But there is also the more satisfactory result that, while the previous ten years' cholera death-rate in jails had been 3·46 per 1,000, the rate for 1884 was less than one-half of this amount. This reduction in the midst of a severe cholera epidemic affords evidence of good work done in many jails.

The chief death causes during 1884 were, dysentery and diarrhœa 12·66, respiratory diseases and phthisis 8·15, and fevers 2·16 per 1,000. Broken down constitutions yielded a rate of 2·95 per 1,000, under the heads of atrophy, anæmia, and dropsy. Leaving these last out of reckoning, nearly the whole of the remaining mortality comes under the head of mitigable or preventible diseases, all of which have of late years undergone marked reduction under improved sanitary administration. If we were to judge solely by the average mortality, the state of Indian jails must be considered as not unfavourable for India, but the real test of progress is not reduced average mortality all over an area, but reduced mortality in districts and circumscribed localities, and, viewed in this way, it is evident that great improvements are required.

46. Of course, the health of prisoners at any given time is the result not of one or two conditions, but of all the circumstances and surroundings of the prison population, such as ages, previous health and disease predisposition, diet, work, and the relation of diet to work, exposure, clothing, climate, locality and neighbourhood, prison construction and arrangements, water-supply, drainage, and such like. Many of these conditions belong to prison administration, and do not come within our sphere, but there are others on which it is our duty to express an opinion, and perhaps the best way of showing what these points are will be simply to abstract very briefly the information contained in the summary of the jail sanitary sheets in the Report under review.

The following items give the number of instances in which defects are noticed in the sheets, but some jails are entered more than once, as having more than one defect:—

Nature of Defect.	Number of Jails in which Defects are stated to exist.
Defective ventilation of dormitories, including excesses	28
Defective construction arrangements	3
Insanitary surroundings of jails	21
Extremes of heat and cold	6
Overcrowding, generally of a temporary kind	63
Bad or unprotected water-supply	15
Bad drainage arrangements of jails and surroundings	23
Damp rooms	2
Bad malarious locality	11
Insufficient clothing	4

To these must be added the necessary results of long occupied undrained sites, especially where the jail sewage has been buried near the buildings, and wherever these exist, and to the extent in which they exist, there are the predisposing causes of the endemic and epidemic diseases shown in the preceding tables.

There is nothing new in the facts, for they have been reproduced year after year in the jail sanitary sheets. There have been frequent discussions on the death-rates of Indian jails and their causes, and there has been an anxious desire to sweep away the excesses in them. But there is one fact that should be clearly kept in view, and this is that the causes of disease predisposition recorded in the sanitary sheets are those observed on the spot by the jail officers, and for practical purposes it is these with which we have to deal. When these defects have been removed it will be quite time enough to discuss the remaining death-rates and their causes.

Besides jails in which there are assigned defects, there are 40 jails in the lists to which no defects are attributed, and, with a few exceptional cases, all these jails are those included under the lowest death-rates in the preceding abstract.

47. In considering the sanitary notes in this jail table, and the use to which the information may be applied without difficulty, it appears to us that if the stations, barracks, and hospitals of European troops were treated with equal fullness, and the details tabulated, we should have less difficulty in tracing back to their causes enteric fever and cholera than we have hitherto had. We have much information about the local sanitary defects of jails which we would earnestly desire to see turned to account, and at present we should be glad of similar information about European stations, descending even to the sanitary details of individual barrack blocks.

48. *Sanitary History of the Civil Population of India for the Year* 1884.—In our memoranda on the sanitary reports of the different Governments we have entered on the details presented by each, and we shall, under the present head, give a summary of the year's results for the populations of India as a whole.

The population making returns of deaths in 1884 amounted to 197,713,629, and this number represents the maximum registration area having a surface of 839,723 square miles. But the birth registration is not yet coterminous with that of deaths, because in Bengal births are as yet registered in only 47 municipalities and towns, having a population of 1,685,651, and the population of districts within which town births are registered is 133,235,391. The actual number of births for the whole population of India cannot yet be arrived at, but in each of our Memoranda we have given the numbers for the Government.

49. The following were the mean birth-rates in each group:—

	Births per 1,000 of Population (means).
Bengal, 47 municipalities	23·51
North-West Provinces and Oudh	43·77
Punjab	42·98
Central Provinces	41·75
Berar	41·30
British Burma	22·66
Assam	26·61
Madras Presidency	29·30
Bombay	32·50
Mysore	23·20
Coorg	14·87

Some of the rates are more near accuracy than are others, but as yet the birth-rates are only approximations to the truth.

50. The total deaths registered from all causes amounted to 5,225,962, or nearly 26½ per 1,000 of the registering population, which is a closer approximation to the true death-rate than has been hitherto arrived at. Of course it is still far short of the truth for a country of great epidemics.

51. The next table copied in abstract from the Report gives interesting information regarding the registration of deaths in each Government:—

Provinces.	Number of Registration Circles.		Population.		Deaths per 1,000.		
	Rural.	Town.	Rural.	Town.	Rural.	Town.	Total.
Bengal	553	96	63,705,518	2,458,366	20·58	27·43	20·83
North-West Provinces and Oudh	1,044	102	41,358,922	2,748,947	34·78	42·47	35·26
Punjab	395	49	17,512,378	1,310,383	35·	41·	35·04
Central Provinces	95	73	8,060,093	757,092	27·48	25·37	27·30
Berar	109	11	2,491,640	138,378	24·60	27·4	24·6
British Burma	823	20	3,227,854	425,775	16·61	36·65	18·95
Assam	639	22	4,427,384	100,550	29·31	32·09	29·37
Madras Presidency	153	76	26,485,071	1,699,607	22·70	27·70	23·10
Bombay	221	62	14,348,658	2,105,756	24·17	29·25	24·82
Mysore	42	18	3,945,547	240,641	14·96	14·57	14·93
Coorg	5	1	172,075	6,227	15·24	10·44	15·08

This table shows that registration is in a more advanced state in the North-West Provinces and Oudh, and in the Punjab, than in any other Indian Government, but it affords no evidence that the population is more unhealthy. In the other Governments much remains to be done before the real sanitary condition of the people is fully known, but it is quite safe to say, that if the executive sanitary administration for saving life had a more close correspondence with the existing registration machinery for telling us how many people have died from preventable diseases, we should have less to complain of about epidemics. Nearly all the sanitary work is done in the town circles, and if we compare the population of these with the enormous rural populations, we may be better prepared to recognize where work requires to be done.

52. We shall next state the assigned death causes in 1884. They were as follows, and we have added the data for 1883 :—

	1884.	1883.
Cholera	282,815	244,376
Small-pox	332,904	232,363
Fevers	3,806,285	2,879,659
Bowel complaints	274,234	261,623
Injuries	76,588	76,059
All other causes	953,141	889,243
Total registered deaths	5,225,962	4,583,323

These figures show that the deaths from cholera accounted for a very limited part of the year's mortality; that small-pox prevailed as a great epidemic in face of the extensive vaccination service; that the great death cause in 1884, as in previous years, was "fever," and that a large proportion of the deaths is still unaccounted for.

Among the "injuries" were included 8,195 suicides and 23,028 deaths from snake-bite and wild beasts, but the former are not stated separately.

53. The next abstract enables us to compare the death-rates from these diseases in each Government in 1884.

Provinces.	Death-rates per 1,000 of Population.					
	Cholera.	Small-pox.	Fevers.	Bowel Complaints.	Injuries.	All other Causes.
Bengal	2·03	·28	14·60	·88	·37	2·66
Assam	4·92	4 0	14·69	3·56	·26	4·87
North-West Provinces and Oudh	·68	·59	24·35	1·73	·48	3·42
Punjab	·03	·87	24·71	·97	·29	8·16
Central Provinces	·02	·55	16·48	2·49	·51	7·25
Berar	·03	·20	11·60	3·50	·40	8·90
British Burma	1·51	1·67	8·08	1·02	·14	6·53
Madras Presidency	2·70	2·10	7·60	1·00	·40	9·10
Bombay ,,	·84	·88	16·83	2·19	·34	3·74
Mysore ,,	·08	·77	7·98	1·19	·26	4·71
Coorg	—	·61	12·85	·50	·18	·94

From cholera, Assam and Madras suffered most severely, next followed Bengal, and in the other Governments cholera was of little importance. The small-pox epidemic of 1884 fell with great

violence on the North-West Provinces and Oudh, where no fewer than 202,541 victims died of it. This, however, was only a part of the loss, for in 1883 there were 138,641 deaths from the disease, giving for the two years no fewer than 341,182 deaths in these provinces, where for many years an active and apparently not inefficient vaccination service had been in existence. The average annual vaccinations reported as successful during five years preceding 1884 were 622,394, and in the latter year 568,372. This experience merely shows that without calling in question the modifying influence of vaccination in ordinary years, it cannot be depended on for safety during epidemics.

Diseases classed as fevers were most fatal in these same provinces and in the Punjab, where they are connected with local irrigation works, defective drainage, and bad habitations of the working classes.

54. The facts, as a whole, show that there was a large increase of deaths among the Native population in 1884; that this increase amounted to 642,639 in the death registration; that it was made up by an addition of 38,539 deaths from cholera, 100,541 deaths from small-pox, 426,626 deaths from fevers, and 12,612 deaths from bowel complaints. The entire year's increase and more was due solely to epidemics, and this fact affords the only clue to the required remedies. The epidemic and local causes in India are quite well known, but up to the present time the epidemic statistics show conclusively that little or no reduction of them has been made by the sanitary executive, where there happens to be one.

55. So far as the few notes on the sanitary condition of stations of British troops quoted from medical officers reports by the Sanitary Commissioner afford us any guidance, they show not that adequate local causes did not exist, but only that the persons charged with discovery and dealing with them failed to discover them. This is further shown by exceptional cases in which patent causes are described and cholera followed.

56. The Sanitary Commissioner states that of 26 communities of British troops attacked by cholera, in 21 diarrhœa is stated not to have been present, and in only five out of 21 Native communties was diarrhœa observed. The experience is certainly not usual, and we should expect that the disease history would show sudden attacks if we had it before us. It is not necessary that diarrhœa should exist for weeks or even for days before attack, a few hours of neglected bowel discharge may make all the difference in the result of a cholera attack.

57. In continuation of the experience of liability to attacks of cholera among attendants, it is stated that 411 cases of cholera were attended by 893 persons, of whom nine were attacked. The facts when analysed yield the following results:

There were 132 cases of cholera among British troops attended by 364 persons, of whom two were attacked.

Among Native troops, 66 cases were attended by 277 persons, of whom none were attacked.

Most of the attacks really took place among officials within jails, of whom 252 attended on 163 cases of cholera and seven were attached. These were of course exposed to local jail conditions.

58. The effect of removal of troops from cholera-stricken localities was "as usual most beneficial "among British troops. Cholera appeared in 26 communities, and in 15 of these movements were "made into camp, in three to different barracks, and in eight the disease occurred in an isolated "form, and no movement was considered necessary. In 10 of the 15 movements into camp no "further case occurred after movement."

Then next follows this statement:—"At Allahabad, where 19 cases occurred in all, only one man "was attacked after the affected community moved into camp." Now the statistics inform us that there were six deaths from cholera out of 789 men at Allahabad, or 7·60 per 1,000, a result which appears to justify the question on what principle the men were kept there and not removed at once. At Meerut there were cholera cases after removal into camp, but in this case we require dates of first appearance of cholera and dates of removal, and, moreover, we should have the cholera history of the country where the camps were formed.

We desire to repeat what we have often said, namely, that when cholera breaks out at a station it has already become a cholera locality, as much so indeed as an attacked village. Movement must be made whenever reasonable suspicion of this matter exists, and if it is delayed until successive cases show themselves, we must not be surprised if cholera appears in camp. Besides this, if local knowledge tells us where cholera is or is likely to be, we must not go there to meet it, we must go elsewhere.

59. *Vaccination service.*—We have already stated the leading facts regarding the small-pox epidemic of 1884, and we shall next give briefly the results of vaccinations over the whole of India for the same year.

The vaccination staff was constituted as follows:—

Sanitary Commissioners	9
Deputy ditto	14
Superintendents	45*
Deputy ditto	21
Native ditto	277
Average vaccinators	3,895†
Total staff	4,261†

The total number of persons vaccinated in 1884 by this special establishment amounted to no fewer than 5,834,871. The total primary vaccinations were 4,443,246, and there were 84,700

* Including Civil Surgeons. † Including 1,067 licensed vaccinators.

successful re-vaccinations. Of the successful vaccinations 1,752,370 were performed in children under one year of age, and 2,113,443 between the ages of one and six years. To this work of the special establishment has to be added 237,342 successful primary vaccinations performed at the dispensaries, of which 66,568 were under one year of age.

The births are estimated in one of the tables, on a ratio of 40 per 1,000 of the population, at 7,538,206, which is probably above the real number, while the successful vaccinations under one year reached only 1,828,059, or less than a fourth part of the estimated births.

This is the only safe way of testing the probable effect of vaccination, for whatever the number of vaccinations above one year may amount to, we have added year by year some millions of infants who are the most susceptible subjects to attacks of small-pox, only one fourth part of the number being protected. Notwithstanding the very great amount of work shown by the tables, it cannot be said that the direction taken by it is altogether satisfactory. But withall, we must remember that small-pox is not only a disease to be modified, but it may become at any time, as it did in 1884, a great epidemic, to be met only by sanitary measures and works in localities.

60. *Sanitary Works (Military).*—The only information under this head, which forms Section VIII. of the Report, is the following summary of expenditure:—

	Rs.
Original works	2,025,943
Repairs	1,761,009
Establishment	1,434,978
Tools and plant	49,854
Barrack Department	478,246
Total	5,750,030

Under the same head are given brief notes bearing on the sanitary state of 69 cantonments in Bengal Presidency. They are not sanitary reports properly so called, and they deal with general rather than with local disease causes, and the diseases connected with them. Take the following as examples:—At Chunar there were 77 British troops with a death-rate of 25·97 per 1,000. These 77 men yielded no fewer than nine admissions from enteric fever, of which, however, all recovered. The only note on these cases is "enteric fever was prevalent among the British troops during the "first five weeks of the year."

At Benares, in 10 months, 318 men yielded eight cases and three deaths from enteric fever, and the remark is "enteric fever during August, September, and October, due to climatic causes."

Allahabad, out of 789 men, had two non-fatal cases of enteric fever, but it yielded 11 cases and six deaths from cholera. The note on this case is more explicit; it is as follows:—"Fevers in "August, September, and October, due to climatic causes and malaria. The ground on which the "E. I. barracks are built is somewhat low and damp, and its surface drainage admits of improvement. "Recommended that the ground in the immediate vicinity of the barracks of the Royal Artillery "and British Infantry be broken up and sown with grass seed."

Lucknow, out of a strength of 2,115 men, had 55 cases and nine deaths from enteric fever and two fatal cases of cholera, and the Report assigns as causes "a large number of men being young "and recent arrivals in the country. The trenches should be at some distance from the barracks." It need scarcely be said that, with so large a force, the night-soil should be disposed of away from the cantonment site altogether.

Meerut had a strength of 1,682 men. It had 21 cases of enteric fever, of which five proved fatal. It had besides 28 cases and 13 deaths from cholera. The note on these losses is as follows:—"Cholera probably due to insanitary conditions and seasonal influences. Ague due to unusual heavy "rains, and malarious fevers to insanitary and seasonal influences."

The cause most generally assigned for sickness is malaria, but in no case, so far as we know, has any attempt been made to deal with purely local malarial causes in the immediate vicinity of the barracks themselves, or by ventilating underneath the barrack floors. It is many years since we advised that trials of works such as these should be made.

61. Under the head of "Sanitary Works, Civil," there is nothing calling for special remark, as we have already dealt with the subject in our Memoranda on the proceedings in each separate Government. This Section IX. merely gives a brief sketch of the year's results.

62. *General remarks.*—The most interesting practical subject dealt with in this section is the result up to the present time of the application of sanitary principles to the protection of health during the Mecca pilgrimages. Until of late years, little was known of the conditions under which these assemblages were held, although from the little that was known it was safely inferred that they partook largely of the character of ordinary large and crowded Indian festivals as those existed in the older time. If any cholera was about it was almost certain to alight at Mecca, and then the blame was laid anywhere than on the right shoulders. The present state of matters will be best described in the words of the Sanitary Commissioner: he says, "The complete immunity from "cholera enjoyed by the pilgrims to Mecca during the Haj of 1884, together with the diminished "prevalence of sickness generally, is most gratifying evidence of the beneficial effects of a stricter "attention to sanitation. Vice-Consul Dr. Abdur Razzak, in his excellent report on the health of "the pilgrims, pertinently remarks with reference to the absence of cholera that this will doubtless "be attributed by some to the increased vigilance displayed by the Turkish authorities during the "year in connection with quarantine, but he proceeds to show that the result may, with greater "probability, be traced to local natural and artificial causes. The sanitary condition of Mecca and

" Moona was greatly improved, surface cleanliness and conservancy having been carefully attended " to. Moreover, the water-supply for the use of pilgrims at Moona was of much better quality." " Slaughter sheds also were erected at distances from one another, instead of being aggregated " together as formerly, and arrangements were made for burying the carcases of sacrificed animals, " instead of allowing them to putrify on the surface. The encamping ground was more openly " occupied, a larger space having been available owing to the absence of Persian pilgrims. . . " Together with this greater attention to the elementary rules of sanitation, the weather was " unusually favourable, heat was less, and cool breezes prevailed at times. It seems, therefore, more " reasonable to ascribe the immunity from cholera and the lessened prevalence of disease generally " among the pilgrims to those causes than to look for an explanation of the absence of cholera to " imperfectly conducted measures of quarantine. The futility of quarantine, even when enforced " with every possible rigour, has been demonstrated time after time, and has been admitted at the " recent International Conference assembled at Rome by some of the most advanced contagionists."

63. Although this favourable experience has only been for one season, the sanitary measures adopted, so far as we can judge of them, were those most likely to bring about the result. But everything depends on their rigourous and continuous application, and as this Mecca cholera has an important bearing on commercial interests it should be a matter of public concern to see that this is done.

64. The only other matter requiring notice is the first result arrived at by Surgeon-Major Dr. D. Cunningham in tracing the life history of the so-called comma-bacillus in the new pathological laboratory at Calcutta. This inquiry is contained in Part I. of the new Scientific Memoirs of Medical Officers of the Army in India, which includes two papers (4). "On the relation of Cholera " to Schizomycete Organisms;" (2) also by Dr. Cunningham "On the presence of peculiar Parasitic " Organisms in the Tissue of a specimen of Delhi Boil."

The first paper confirms the observations of Dr. Koch and Drs. Klein and Gibbes as to the occurrence of the curved bacillus in cases of cholera, and also of a curved bacillus elsewhere, having a different life history from Dr. Koch's form. It is also shown that the true comma-bacillus of Dr. Koch is an organism subject to metamorphosis, and presenting very different characters when cultivated under different media, but for our practical purposes this brings us no nearer our end than we were. Only it is shown that Dr. Koch's organism is an inhabitant of Calcutta foul water tanks where no cholera existed in the vicinity. This paper is merely a first and very necessary instalment of the work which will, no doubt, be ably carried through by Dr. Cunningham. His conclusion in regard to the Delhi sore is that the disease processes may " certainly be associated with, and possibly " caused by, the presence of peculiar parasitic bodies. In regard to this, however, it appears to be " quite possible that such bodies may constitute a real cause of such disease without necessarily " constituting its only cause."

65. In conclusion, the large amount of interesting information on the whole sanitary history of India contained in this Report of the Sanitary Commissioner and in Dr. Stephen's statistical tables helps to bring out certain definite results of great practical importance. First among these is, that for another year the death-rate of British troops has held the favourable position which it attained in 1883, with only a slight addition from cholera at one group of Bengal stations.

The statistics for the Native Army show similar results as those of the preceding year.

The chief death cause in the European Army in India is enteric fever, from which, in 1884, the admission-rate was 11·7 per 1,000 and the death-rate 2·34 per 1,000; ratios which may be contrasted with those for the Home Army in 1883, which yielded 1·3 per 1,000 admissions and ·24 per 1,000 deaths. The Indian admission-rate was ninefold and the death-rate twelvefold that of the Army at home. The contrast is otherwise of importance, because it shows that, as both the Indian and Home Armies contain many young men, there must be some other factor besides youth to account for this difference of liability to fatal fever. No doubt heat and other climatic influences add to enteric fever liability in India, but the amount of this liability cannot be estimated until we shall have freed Indian stations from these local fever causes which we know from home experience to be connected with liability to enteric fever in the colder climate of home stations. There is plenty of evidence to show that these local causes are closely related to the subsoil conditions under and around barracks in India, and that it would be very advisable to deal practically with at least one enteric fever station on this ground. There is also experience to show that enteric fever stations are liable to outbreaks of cholera, and the relation of local insanitary conditions to the latter disease is proved by the arrest put on it by the removal of troops. It is even not at all improbable that change from an enteric fever station into a healthy camp might be of use.

But another local cause of enteric fever, known both at home and in India, is neighbourhood of unhealthy and insanitary localities and population, and it is here that the sanitary state of European troops connects itself with the sanitary state of the Native population.

Without calling in question the difficulties of this aspect of the case, we cannot escape from the statistical facts showing the great losses in many ways which India has to bear from the prevalence of great epidemics, the local causes of which have been long made out. We are bound in the interests of the public health to recommend that these causes should be grappled with firmly on the principles we have laid down in former Memoranda, as well as in our suggestions for the improvement of Indian stations and their vicinity reissued in 1882.

This recommendation, together with the removal of local subsoil causes of enteric fever and other epidemics at European stations, are the principal conclusions of a practical kind deducible from the Report under review.

22nd June 1886.

No. 2.

Memorandum of the Army Sanitary Commission on the Report of the Sanitary Commissioner for Madras for 1884.

1. The population of Madras Presidency at the last census in 1881, and exclusive of Europeans and Eurasians, was 30,835,771. But the number from which returns of births and deaths were received in 1884 amounted to 28,151,052.

2. The births registered among this population were 423,108 males and 404,273 females, together 827,381, yielding a birth-rate of 29·3 per 1,000, probably under the truth, as the rates varied considerably in different districts. The lowest rate, 17·1 per 1,000, was returned from the Nilgiris, and the highest, 41·4 per 1,000, from Chingleput. The average male births were 104·6 to 100 births of females.

3. The same population returned 334,044 deaths of males and 316,291 deaths of females, together 650,335, equal to a death-rate of 23·1 per 1,000. Of males 105·6 died for every 100 females. The lowest district death-rate registered was 14·5 per 1,000 in Ganjam and Nellore. The highest was 49·4 in Madras. The lower rates are too low, but the nearly 5 per cent. death-rate for Madras is apparently too high, possibly from under-estimating the population. The fact, however, appears to be that, out of an assumed population of 389,984, the registered deaths were 19,279. Taken according to sex, the male deaths were 50·05 per 1,000 and the female deaths 48·3 per 1,000. Here, surely, is a case calling for very active interference, for if this state of matters is allowed to continue Madras may have the unenviable reputation of being the most unhealthy city in India.

4. The next abstract shows the deaths returned according to age in 1884:—

Under one year	141,872
One and under 15	173,703
15 to 50	201,268
Over 50	133,492

These figures are only rough approximations to the facts, for the mortality of infants is apparently too low when the sanitary state of Madras Presidency is considered.

5. The next abstract gives the death causes of the year:—

Diseases.	Deaths.	Deaths per 1,000 of Population.
Cholera	75,476	2·6
Small-pox	61,347	2·1
Fever	215,977	7·6
Bowel complaints	28,775	1·0
Injuries	11,502	0·4
All other causes	257,358	9·1
All causes	630,335	23·0

The previous five years' death-rate was 17·2 per 1,000, but this rate and the rate of 23 per 1,000 for the year 1884 are both much below the truth. All that the table shows is that more deaths were registered in 1884 than the average of previous years.

6. Registration is better done in the towns than in the districts, as is shown by the fact that the average death-rate for 76 towns was 23·7 per 1,000, against a previous five years' average of 23·8 per 1,000, while the district rate was 22·7 in 1884, and the previous five years' rate was 16·8 per 1,000.

7. We shall next give a brief sketch of the disease history of 1884, beginning with cholera.

The year 1866 was remarkable for its great loss of life from cholera, amounting to no fewer than 200,961 deaths. This great epidemic was followed by a brief period of decline and increase until the next maximum year, 1870, when there were 55,867 deaths. The annual cholera mortality thereafter declined until it reached its lowest registered rate, which was only 313 deaths in 1875, but there succeeded to this time of quiescence a great epidemic outbreak, culminating in 357,430 deaths in 1877. The mortality then declined to 613 deaths in 1880, when there came another epidemic period, still apparently in progress, for since that year the recorded cholera mortality has been as follows:—

Years.	Cholera Deaths.
1881	9,446
1882	23,604
1883	36,284
1884	75,476

8. During the last of these years cholera deaths were returned from all the 22 districts, with the exception of South Canara. But the epidemic was very unequally distributed. The lowest rate, 0·007 per 1,000, was returned from Vizagapatam, and the highest was 11·1 per 1,000 from Tanjore. Of the 76 towns, nine escaped the disease, while all the others suffered more or less. The town rates varied from scarcely appreciable ratios to some of the highest rates on record. There were town ratios of 10, 12, 14, and above 15 per 1,000, and two towns, Rajahpoliem and Sivagiri, had death-rates of

52·7 and 63·4 per 1,000. The conjoined population of these two towns was, it is true, not large, only 25,653, but, nevertheless, 1,946 of them were cut off. They appear to afford examples of intense *local explosions, which were not* unfrequent, and made up the death-rate, rather than by extent of *epidemic prevalence. There are* 229 registration circles in Madras, 178 of which returned cholera *deaths, and out of 52,051 villages* 7,225 yielded all the district deaths, or on an average of 10 per *village.*

9. *As will* be seen from the following abstract, cholera prevailed during every month of 1884 :—

Months.	Cholera Deaths.	Months.	Cholera Deaths.
January - -	21,268	July - -	6,267
February - -	7,562	August - -	3,298
March - -	2,374	September - -	2,677
April - -	1,550	October - -	1,645
May - -	2,[illegible]8	November - -	3,639
June - -	3,975	December - -	19,313

10. In the course of the year the office of sanitary commissioner was transferred from Dr. Furnell to Dr. Bidie, and there was consequently no information available on which any account of the sanitary condition of affected localities could be based, but Dr. Furnell has promised a special report on the subject. One very important conclusion may, however, be drawn, and this is, that the epidemic cholera of 1884 has published its own report in the local death statistics, and, when taken in connexion with the past history of the disease in the Presidency, it has proclaimed distinctly enough that responsibility rests somewhere for the immense losses which have fallen on the people. There is one district, Tanjore, in which cholera has been prevalent ever since registration has been introduced. In this single district all the 14 registration circles furnished deaths from cholera, as did also 1,977 villages out of 3,551, and 23,671 people died of it. The death-rate was 11·1 per 1,000, against a previous five years' average of 1·8 per 1,000.

The present Report informs us that these facts "caused much anxiety to Government," and an inquiry was invited. Some examination was made, but in a case like this we ought to have had an exhaustive sanitary report on the whole area and its villages, and the special causes of the mortality ought to have been distinctly traced, and steps taken at once to save life by their removal. This is what naturally would have been done in England in former days. But instead of this course, we have no report at all, and only unproved surmises that "the conditions of soil and water in Tanjore are "very similar to those in Bengal, and that the habits of the people contribute to keep up cholera in "their midst. They live on irrigated land. The country is wealthy, but the actual labourers are "very poor, and live in wretched hovels built on a damp porous soil." It is apparently taken for granted that these conditions, even if they were all, must remain permanent, and as a natural result the people must suffer. There is only one practical fact mentioned, and this is, that the water becomes green, foul, and unfit for use, especially in dry weather. But this view does not help us much, for we find that the rainfall in October, November, and December 1883 in Tanjore district amounted to above 27 inches, and, nevertheless, that in January 1884 no fewer than 7,688 people died of cholera. The fact is, we require to have the removable causes discovered and dealt with by skilled sanitary and engineering aid. Dr. Bidie has said, with perfect truth, that "the general death roll of the "Presidency will show how much has yet to be done to protect the people of Southern India from "epidemic disease, and that our efforts must not be confined to periods when sickness is prevailing, "but be continuous and systematic. Fortunately, too, the sanitary precautions which have been "found most effectual in warding off cholera are equally valuable for the prevention of other diseases."

In this statement the necessities of the case are fully recognised, and a great change would soon come over the public health of the Presidency if sanitary work in some degree corresponded to them.

11. *Small-pox.*—With the single exception of the famine year 1877, when there were 88,321 deaths from small-pox, the mortality in 1884, which amounted to 61,247, was the highest of 14 years. During the years succeeding the famine there was a reduction in the mortality, which sank to 0·5 per 1,000 in 1880 and 1881. In 1882 the rate rose to 0·6. In 1883 it was 1·3, or more than doubled, and in 1884 it was 2·1 per 1,000, against a previous five years' average rate of 0·7, or just one third.

All the districts, and 226 registration circles out of 229, registered small-pox deaths, but the number of villages affected had not been returned. Of 76 towns 65 yielded small-pox deaths, 4,063 in number, or 2·1 per 1,000 of the town population, the same rate as that registered in the districts.

12. The following were the monthly deaths :—

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January - -	5,237	July - -	4,850
February - -	6,771	August - -	4,381
March - -	8,257	September - -	3,923
April - -	6,474	October - -	3,444
May - -	5,207	November - -	3,220
June - -	4,799	December - -	4,648

These deaths, according to age, stood as follows :—

Under one year	11,781
One and under 12 years	27,511
Above 12 years	21,955
Total	61,247

Dr. Bidie points out that nearly 64 per cent. of the year's loss from small-pox fell on ages under 12, while in Madras town the deaths of children under three years of age equalled 74 per cent. of the total deaths. The history as a whole leads to two conclusions: 1st, that there is a high degree of epidemic susceptibility to the action of small-pox, and, 2nd, that much improvement is required in the vaccination service.

Madras town and district had a small-pox death-rate of 9·8 per 1,000. But the highest district rates properly so called were those of Godavari and Kistna, respectively 6·8 and 6·1 per 1,000. Several of the town rates were very high. For example, Rajahmundry yielded a rate of 11·6, and Ellore 13·2 per 1,000, while Cochin, out of a population of 15,698, lost 364 by small-pox, or a rate of 23·1 per 1,000.

13. The vaccination establishment for 1884 stood as follows :—

Inspector of Vaccination and Deputy Sanitary Commissioner	1
First class Deputy Inspectors	33
Second „ „ „	15
First class Vaccinators	208
Second „ „	354
Probationers	110
Peons	48
Total	769

14. Including the probationers, there were thus 672 officials engaged in the actual work of vaccination, and the next abstract shows the year's results for the civil population (exclusive of military police, jails, &c.) :—

Population of circles and districts, 29,138,686.

Successful primary vaccinations,—

Under one year	103,114
One, and under six years	322,826
	425,940
Total, all ages	596,948
Successful re-vaccinations	3,291

These figures give 94·1 per cent. of successful primary vaccinations.

The general results for the country population were as follow during the last five years :—

Average annual successful vaccinations per 1,000	16·2
Average small-pox deaths per 1,000	0·6

The corresponding data for 48 municipalities were the following :—

Population	1,733,350
Successful primary vaccinations,—	
Under one year	25,715
One, and under six years	40,379
	66,094
Total, all ages	88,281

The five year's ratio of successful vaccinations per 1,000 in the municipalities was 41·1, and of small-pox deaths 1·4.

These data are no doubt approximately correct, and we can deduce from them what amount of protection was afforded to the population by assuming the registered births as approximately correct.

The facts would stand thus :—

Registered births	827,381
Vaccinations under one year of age	131,301
The birth ratio was	29·3 per 1,000
Vaccinations under one year	4·2 „

The vaccinations under one year were not much more than a seventh of the births, a fact which may in some sense account for the great prevalence of small-pox at the younger ages, which yielded not far short of two thirds of the mortality. The remedy suggested by the year's experience is that the Madras vaccination service should be directed to overtaking the births at ages under one year. But the great predisposition to small-pox epidemics in Madras Presidency must be met by strenuous endeavours to improve the sanitary condition of the population. The facts in the present Report show how small is the influence of vaccination in warding off small-pox when the predisposing epidemic causes are put on one side.

15. In Madras itself, Dr. Bidie says, "the disease was most destructive amongst children, and, as "might be anticipated, it raged with greatest severity in the most crowded and dirtiest quarters of "the town." This statement includes in a few words both the causes and remedies.

16. *Fevers*, like other death causes, bore evidence of the high susceptibility of the population to these causes during the year under review. The annual fever deaths registered during the last 19 years, if the registration had been all along equally reliable, would have proved a very large increase in fever mortality. Thus during the earlier years of the period the annual fever deaths may be estimated at about 110,000, but this was when registration was in its infancy. Since 1869, however, the fever deaths registered have been on the increase, and may have averaged double the record of the earlier years until the famine intervened and raised the fever mortality to the enormous number of 469,241 for the year 1877, and 374,443 for 1878. After the latter year the number of fever deaths registered declined year by year to 188,561 in 1882, and there is now a tendency to increase, for in 1883 there were 203,786 fever deaths registered, while in 1884 the mortality had reached 215,977 registered deaths. This number nearly averaged the previous five years' rate, which was 7·6 per 1,000, but this rate included the remains of the famine fever of 1877–78. All the districts and all the registration circles in them returned fever deaths in 1884. The number of villages attacked is not given in the returns, but it may be doubted if any of them escaped.

17. The lowest district fever rate of the year was returned from Tanjore. It was 4·9 per 1,000 only, marking apparently defective registration. Seven districts yielded rates exceeding 10 per 1,000. The highest rate of the year, 15·4 per 1,000, was returned from Kurnool district. All the 76 towns registered fever deaths, 8,850 in number, or 5·2 per 1,000, or about 2½ per 1,000 under the general Presidency rate. Only seven towns had fever rates of 10 per 1,000 and above. The highest rate of the year, 15·1 per 1,000, was returned from Vizianagram.

18. The following abstract shows the fever mortality for each month:—

Months.	Fever Deaths.	Months.	Fever Deaths.
January	20,816	July	18,414
February	15,864	August	18,530
March	14,958	September	18,218
April	14,166	October	17,930
May	15,398	November	21,088
June	16,248	December	24,247

19. The Report contains no information as to local conditions accompanying these fever deaths. Nevertheless, every attacked village and town could supply information. But still better would it be if the details already obtained were put to practical use. If village sites were drained and otherwise improved, villages, houses, and compounds cleansed, and their water-supply protected and improved, we might confidently expect reduction of these great and preventable death-rates. The measures required are purely practical, and our desire for information might admit of an answer that there had been quite enough reporting already, but far too little effective sanitary work.

20. *Bowel complaints.*—The registered deaths under this head were 28,775, or 1 per 1,000 of the population, the previous five years' average having been 0·7 per 1,000. The deaths were widely distributed, inasmuch as all the registering circles, with three exceptions, made returns of them. Of the total bowel complaint deaths, 4,201 were registered in the towns, which thus yielded a death-rate of 2·4 per 1,000, or nearly two and a half times that of the Presidency. There was a certain synchronism between the monthly deaths from bowel complaints and those from cholera.

21. *Injuries.*—Deaths so classed included 1,514 suicides, 861 from wounds, 6,837 from accidents, and 2,290 from wild beasts and snake bite.

22. *All other causes.*—The total mortality for Madras Presidency was made up of 650,335 deaths, and those entered under the present head were 257,358. A comparison of the two sets of figures will show how much improved registering work is still required to complete the disease history of the Presidency.

23. *European Troops.*—The strength of European troops serving in Madras Presidency on the 1st January 1884 was 10,774, and after making allowance for the year's additions and reductions, the strength on 1st January 1885 was 11,220.

The ratios from the usual inefficiency causes during 1884 were as follows:—

	Ratios per 1,000.
Admissions	1106·1
Daily sick	59·1
Deaths	8·5
Invaliding for change	20·9
Invaliding for discharge	11·4

The year's death-rate was the lowest on record and much below the average of previous years. The admissions, daily sick, and invaliding were also considerably under the average. "Fevers and "venereal diseases were the most common causes of inefficiency throughout the force."

24. There were 768 admissions to hospital from intermittent fever, of which one half came from a single station, Kamptee, which in times past has been the chief fever centre for Madras troops. A table in the report shows that during the last seven years there have been 12,497 admissions from intermittent fever at 20 stations, and of these admissions 3,010 were furnished by Kamptee alone.

25. The most fatal fever was enteric fever, from which there were 129 admissions and 18 deaths. Of the enteric fever cases, 60 were admitted at Bangalore, 39 at Secunderabad, and 15 at Kamptee. We are glad to learn from the present report that the foul water supply at Bangalore is at last likely to be abolished, after having been allowed to do mischief to the troops for a quarter of a century.

26. *Cholera* yielded 12 admissions and 10 deaths at Bangalore, Kamptee, Madras, Poonamallee, St. Thomas' Mount, and Secunderabad.

27. *Small-pox* yielded 19 cases, of which nine cases and one death were admitted at Bangalore. It is worthy of remark that while cholera gave rise to a death-rate of 2·6 per 1,000 among the whole civil population in affected and unaffected districts, the death-rate among European troops was under one per 1,000.

28. Admissions from venereal diseases show no tendency to reduction. The admission ratios for the last five years have been as follow :—

Years.	Ratio per 1,000 strength.
1880	256·2
1881	220·0
1882	257·3
1883	243·2
1884	256·1

These figures justify the conclusion of the Sanitary Commissioner that "all our efforts to improve "matters have been of no avail."

A 25½ per cent. admission-rate from these diseases appears to be the normal state of matters at present which may be contrasted with the 2½ rate among native troops.

29. The sick and death rates varied considerably at different stations of European troops. As usually happens, the highest and lowest rates were returned from small bodies of troops. For example, Mallapuram, out of a strength of 95, returned a death-rate of 31½ per 1,000, but there were only 3 deaths, only 1 of which was from zymotic disease, viz., fever. On the other hand, Bangalore, with a strength of 2,067, had only 8 deaths, or 3·8 per 1,000, and of the deaths 1 was from fever, 3 from cholera, and 1 from small-pox. Secunderabad, out of a strength of 2,386, yielded 23 deaths, or 9·6 per 1,000, of which 10 were from fever and 1 from cholera. The lowest death-rate of the year was yielded by Wellington, where out of 554 men 2 died, equal to 3·6 per 1,000. The highest rate of any large station was 16 per 1,000 out of 682 men, in Madras. Three of the 11 deaths there were from cholera. There is nothing in the present year's report to modify the estimate in previous ones of the relative sanitary condition of European stations. But, so far as can be judged of by the statistics, these bear evidence of steadily improving healthiness. As a general principle, improvements should be pressed forwards at the largest stations.

30. *Native Army.*—The total strength of the Native Army averaged 29,150, and the inefficiency rates were as follow :—

	Ratios per 1,000.
Admissions	749·2
Daily sick	32·8
Deaths in hospital	9·0
„ out of hospital	2·6
Invaliding	21·1

The strength present on which the stational statistics are based was 24,337. Out of this number, the deaths in hospital were 221 = 9 per 1,000. Of the deaths in hospital, 5 were from small-pox, 39 from fevers, and 29 from cholera. The highest death-rate of the year, 22·7 per 1,000, took place at Secunderabad, out of a strength of 3,388; but out of 509 men at Palaveram, while the deaths in hospital were 9·8, those out of hospital were 19·6 per 1,000. Of the Secunderabad deaths, 5 were due to fever and 22 to cholera. The health of European troops contrasts favourably with that of Native troops as regards death-rates. The admission and sick rates were both higher. But, in the case of fevers, the admission-rate of Native troops on an average of Native stations was 281 per 1,000 as contrasted with 179 per 1,000 for British troops. As regards the total admissions among British troops, which averaged 1,106·1 per 1,000, 256·1 were due to venereal diseases. Deducting these, the admission-rate for all other diseases would be 850 per 1,000, and, making a corresponding reduction for Native troops, their rate would remain at 717 per 1,000, not so great a difference for strangers in a sub-tropical country.

The apparently higher admission-rate among European troops does not, therefore, militate against the general improvement of Army health, but, when the facts are looked at in connexion with the

national statistics, it is easy to lay the hand on the defaulters, and to show where better work and more of it is required.

31. *Sanitary Reports (Military).*—Under this head are given 31 abstracts, sent to the Sanitary Commissioner from as many cantonments of British and Native troops.

Their nature is accurately described by the Sanitary Commissioner in the following words:—"These reports are mostly so perfunctorily drawn up, and the information they contain is so meagre, "that they are practically of very little use." They afford no information on the reasons why certain stations are more unhealthy than others, or on any remedies proposed for improving their sanitary condition. Current surface work is carried out, and this is so far well, but of really efficient sanitary improvements, it would not be easy to find a trace. We are, however, promised that "an "effort will be made to obtain more detailed and useful information for future reports." But except at certain unhealthy stations to which we have already referred, and where work of a different kind is required, there has been work done in surface cleansing, and surface drainage and water-supply, which has, no doubt, improved the general health of the Madras stations.

32. *Jails.*—The prisoners remaining at the end of 1883 numbered 7,437, and those at the end of 1884 were 6,596. Of the average prison population (7,017), 147 died of disease. In previous Memoranda we have given the yearly vital statistics, as affording the best guides to the state of prisons and prisoners, and we shall merely introduce the data since the famine and scarcity years 1877 and 1878, as follows:—

Years.	Ratio per 1,000.	
	Admissions.	Deaths.
1877	971·8	175·4
1878	944·4	125·4
1879	890·5	55·8
1880	854·0	44·7
1881	742·5	41·4
1882	800·4	41·9
1883	865·3	29·4
1884	769·5	20·2

These figures show a great and continuous improvement in the sanitary state of Madras jails, but, like all averages, they do not give an accurate idea of individual facts. There are still jails with very high rates, and these should be separately dealt with. So late as 1882 Trichinopoly Central Jail had a death-rate of 16¼ per cent., and one of only 1·74 per cent. in 1884. If we apply the epidemic test in 1884 this satisfactory conclusion is further confirmed. Thus the town cholera mortality was 5·3 per 1,000, and for the whole province it was 2·6, while the cholera death-rate in the jails was 0·9 per 1,000. The total loss of life from cholera was only 7 deaths, of which 5 took place in Cuddalore jail. But there were only 169 prisoners, and although the town itself suffered somewhat severely, the high jail rate marks the presence of local causes. The entire fever mortality in the jails was only 0·8 per 1,000. There were 1,389 fever admissions, but only 7 deaths. The corresponding fever mortality for the civil population was 7·6 per 1,000. There were 14 cases and 2 deaths from small-pox, or 0·2 per 1,000, or just a tenth part of the civil rate. Our object in introducing these comparisons is simply to call attention to the fact that 7,000 inhabitants out of the population of the Presidency have had their sanitary surroundings so improved as to have nearly escaped epidemics, showing that the work of improvement is a practicable one, and to raise the question why it is that the remainder of the population not in jails suffers so greatly, and why so little effort has been made to improve their sanitary surroundings also?

33. In comparing the vital statistics of the civil population with those of fixed bodies of men some allowance must be made for inaccuracies, but after making every allowance the question raised by the following figures must be answered, the differences accounted for, and these must be shown to be permanent and irremediable by any Government intervention, or they must be removed if reproduced in successive years.

Death-rates per 1,000, 1884:—

Diseases.	Civil Population.	Native Army.	Prisoners.
Cholera	2·6	1·2	0·9
Fever	7·6	1·6	0·8
Small-pox	2·1	0·2	0·2
Total epidemic deaths	12·3	3·0	1·9

These figures contain the year's epidemic results of the sanitary administration of Madras. The facts are taken from the Sanitary Commissioner, whose duty it is to report the annual losses from preventable disease, which it is the duty of the sanitary executive, if there be such a thing, to remove.

14. *Municipalities.*—There are 28 municipalities in the Presidency of Madras, under their own local Governments. Their aggregate population in 1884, including Madras town, was 1,743,350. The births registered in 1885 were 55,152, or 31·8 per 1,000 of the population, and the deaths registered were 58,989, or 34 per 1,000. The deaths were attributed to the following causes :—

	Deaths.
Cholera	7,172
Small-pox	7,689
Fevers	10,668
Bowel complaints	6,464
Injuries	550
All other causes	26,446

The death-rates in these towns have been as follows for the last five years :—

	Per 1,000.
1880	26·6
1881	28·1
1882	28·0
1883	30·0
1884	34·0

The death-rates are rising instead of falling, and if the registered deaths are approximately correct, the proper expression to adopt is that the municipal authorities are shown by the figures not to have done their duty efficiently.

35. As regards their proceedings, the Sanitary Commissioner informs us that "no new work of an "important nature was undertaken during the year." . . . "All that was done consisted, as "usual, in the repairing and cleansing of tanks and wells, and in the repair and construction of "latrines, drains, roads, dustbins, markets, slaughter-houses, &c.," all of them useful and necessary works, but the year's epidemic experience shows that something more is required.

36. As regards actual sanitary condition, the following summary by the Sanitary Commissioner is of importance :—"The sources of water-supply were the same, chiefly tanks and wells, and in some "municipalities rivers and irrigation channels. Year after year greater attention is paid and care "taken to conserve and preserve the sources supplying drinking-water from pollution. Generally "speaking, there is no system of drainage. The existing drains chiefly consist of side cuttings for "surface drainage only. In some towns, however, pucka masonry drains exist. Cesspools abound, "and drainage from houses flows into these, or into backyards, or into the streets, or into the side "cuttings. The system of conservancy was the same as last reported. The street sweepings, other "refuse matters, and contents of latrines and dustbins were removed daily by scavenging establishments, "maintained for the purpose, and carted away beyond municipal limits, and disposed of as usual, either "by burying in trenches, being thrown into fields, sold as manure, or consumed in cinerators."

37. The staff and material employed (excluding those of Madras city) is stated as follows :—

Establishment.	Number.	Material.	Number.
Inspectors	111	Carts	1,024
Overseers	34	Dustbins	4,428
Maistries	71	Public latrines	922
Peons	185	Private latrines	17,131
Sweepers	3,189		
Tank watchers	109		
Total sanitary staff	3,699	—	—

We must, however, repeat the facts already stated, that this staff does sanitary work for 27 towns, excluding the capital, and is intended to supply the wants of 1,327,502 people.

The work done includes the cleansing of 17,131 private latrines, which apparently marks an important advance in sanitary procedure. As the Sanitary Commissioner remarks, private cleansing of this kind, if generally adopted, "would enable municipal servants to obtain access into the interior "and backyards of dwellings, and by this means the cleansing of compounds and inside of houses, "where proper conservancy is most needed, will, it is hoped, be gradually effected." But from what has been already quoted from this Report, it will be seen that the main disease causes are those connected with the fouling of subsoils by cesspits and want of drainage, and the consequent fouling of wells in these places. All the surface cleansing that can be done will not affect materially the conditions of the problem. What is really needed is house drainage and the total abolition of cesspits, and in absence of these fundamental sanitary improvements we must expect the recurrence of epidemic outbursts among the people.

38. The following was the expenditure for sanitary purposes in 47 municipal towns (excluding Madras), the population amounting, as already stated, to 1,327,502, and the staff and material of which has been already enumerated; it will be seen that the last completed year ended in March 1884, and that the returns for the same year were for nine months only.

	1883–84.		1884–85.	
	Amount sanctioned.	Amount spent.	Amount sanctioned.	Spent in Nine Months.
	Rs.	Rs.	Rs.	Rs.
For conservancy	363,476	357,865	378,939	273,576
Improving town sites	44,656	50,196	36,285	18,676
,, water-supply	45,613	44,009	67,097	42,133
For fairs and festivals	3,010	3,826	6,935	2,494
Markets and slaughter-houses	24,688	17,962	20,074	11,842
Other sanitary objects	89,756	68,286	35,206	36,030
Total	571,199	541,644	654,536	384,751

The whole amount sanctioned for the year 1884–85, if it were spent, would be about a shilling a head of the population, apparently a very disproportionate sum for the whole sanitary improvements of a year. The conservancy part of it would be a little over sixpence a head. Small and unsatisfactory as the advance has been, still as compared with past times the Sanitary Commissioner considers that there has been advance. "On the whole," he says, "it may be said that of late "sanitation has made some progress in municipal towns. Much remains to be done, and there is "ample room for improvement," but there is reasonable hope for the future. The main danger with the new municipal authorities is their passing into a wrong groove. We have stated what the local epidemic causes in these towns are, and where they are to be found. They include efficient compound and house cleansing, and, without in the slightest degree detracting from the importance of really efficient surface work, it may be safely said that no amount of this work will compensate for the subsoil pollution caused by house cesspits and the sinking of sewage from the surface into the subsoil. This must be put an end to either by house or town drainage, or by removing the whole town sewage solid and liquid daily by hand labour.

39. The Report contains abstracts of 41 municipal and other town reports which fully bear out the general conclusions we have quoted from the Sanitary Commissioner's Report. It is not necessary to refer to them individually, as the same general principles of improvement are applicable to all of them. If there be an exception it is that of Guntur in Kistna, about the only town in Madras which has had the service of a zealous and active municipality. Of its water-supply, drainage, and conservancy, it is stated that "it is very well off in these respects. Its water-supply is excellent and well taken care "of, drainage good, and conservancy efficient." In the ante-municipal days this town of 19,646 inhabitants was a hotbed of cholera. But since it has been improved on lines strictly applicable to every similar town in India cholera has ceased to infest it. The five years' death-rate of this town had been 16·3 per 1,000, but it had an added rate of 2 per 1,000 from a smart attack of small-pox; it had no cholera, although Kistna district, in which it is situated, yielded 1,561 cholera deaths. The same district had 10,386 small-pox deaths, or 6·7 per 1,000 of the population, while Guntur town escaped with 46 deaths, or 2·3 per 1,000. It may be further stated that Kistna fever-rate was 9 per 1,000, while the Guntur fever-rate was 4·2 per 1,000. We have here an instance of good sanitary work carried out for a number of years, attended by so very marked a diminution of its epidemic death-rates as to justify our advising for another year that its example should be followed.

40. The sanitary establishment and outlay for this town of 19,646 inhabitants was made up of—

4 overseers.	25 carts.
4 peons.	65 dustbins.
35 sweepers.	18 public latrines.
25 public totties.	4,000 private latrines.
4 private totties.	4 tank watchers.

From the way in which the accounts are made up, we have only the amounts expended for nine months ending with December 1884. The estimated income for the whole year, we presume, was Rs. 31,380, and out of this aggregate the outlay for nine months was as follows:—

	Rs.
Conservancy	5,870
Improvements in wells	146
Other sanitary work	110
Total	6,126

If 25 per cent. be added to this total for the other three months the whole year's expenditure for sanitary work, the efficiency of which has been proved for years by its results, would be in round numbers 765*l.*, or little more than 9*d.* per head.

Taking the experience of Guntur, as it has been given in the present and in previous Reports for years past, it appears to show that the sanitary improvement of these Indian towns does not depend so much on the outlay, as it does on the zeal and efficiency with which the work is carried out and superintended by the municipal authorities, and hence it throws some more light on the nature of these improvements in sanitary administration which are so much needed in Madras Presidency.

41. *Local fund circles.*—The most important of all sanitary work in India is that which must be done in these circles, for it is in them that Indian epidemics take their origin and find most of their victims. The number of local fund circles in 1884 corresponded to the number of districts, excluding Madras, so that they were 21 in number; they contained 52,003 villages, and these villages formed the population centres of the entire rural population of the Presidency, which in 1881 numbered 28,109,869 individuals.

The total available income of the year for the local wants of this great population was one third of the land cess amounting to Rs. 1,402,971, in round numbers 140,000*l.*; of this sum 39,967*l.* was allotted for sanitary purposes for the financial year 1883–84, and 30,828*l.* was spent. The allotment for the next year 1884–85 was 37,294*l.*, and the expenditure for the last nine months was 19,745*l.* The completed year's expenditure was only a little more than a farthing per head of the population.

42. The objects on which sanitary expenditure was incurred during the completed year, with the amounts allotted and expended, stood as follows:—

	Whole Year 1884–85.	
	Amount sanctioned.	Amount expended.
	Rs.	Rs.
Conservancy	163,006	154,985
Village sites	40,080	15,611
Water supply	84,581	68,168
Fairs and festivals	10,971	8,839
Markets and slaughter-houses	58,063	26,725
Other sanitary objects	43,016	33,965
Total	399,672	308,288

The medical statistics of district populations have been already discussed. There is no special account of village sanitary conditions, but under the head of "sanitary works" the Sanitary Commissioner states that "they consisted chiefly in the sinking of wells and excavating tanks, in the "erection of latrines and dustbins, improving and repairing drains, cleansing tanks and wells, "removing rank vegetation, improving village sites, &c. Except in a few Cusbah towns, where "some stone drains exist, the drainage is mostly very primitive, consisting of ditches cut in the soil "in the sides of the streets and thoroughfares, and house drainage either flows into these, into "cesspools, or into the backyards, where it sinks into the soil. . . . Out of a total of 52,003 "villages only 565 were conserved, against 576 in 1883."

43. We have placed these two statements side by side to show the points in which existing sanitary necessities are not met by the expenditure, but it is satisfactory to know that something has been done in the way of legislation at least to meet these deficiencies by the Madras Local Boards Act of 1884, which "provides for the prohibition and removal of obstructions, and the cleansing of tanks, "streams, wells, and unwholesome buildings and lands in all rural areas," and the Sanitary Commissioner expects "that greater attention will be paid to village and town sanitation" under the powers conferred by it. But the great want in all villages is cleansing and keeping clean, provision of suitable accommodation for cattle to enable them to be removed from compounds and houses, closing all cesspits and bad wells of houses, and providing village water supplies. Although the Sanitary Commissioner does not include these all important points in his statement, we must hope that they have not been overlooked.

44. A further step was taken in the year 1883 in constituting zillah and civil surgeons, district medical and sanitary officers for their respective districts, "to inspect, as frequently as is consistent "with their other duties . . . . the conservancy establishments of their districts, especially of "the larger towns and villages." We must not forget, however, that the utility of all such inspection work has to be gauged not by the amount of it, but by what comes of it.

45. No amount of inspectors' work can either cleanse or drain a village, or give it good water. To be of use, we must fully acknowledge that the inspector can never be more in public health administration than the immediate forerunner of the executive sanitary officer, for it is he, and not the inspecting officer, whose duty it is to remove disease causes and save life.

46. *General remarks and personal proceedings.*—There is not much information under this head, apparently due to change in the office of Sanitary Commissioner. The chief interest lies in the account given in Dr. Furnell's appended report, already referred to, on the result of an inspection made by him into the causes of cholera in Tanjore district, which he concludes has been mainly due in past times to bad and deficient water supply.

The facts he mentions leave no doubt that the water is both bad and deficient, and we are glad that the Collector has been desired by the Government "to give the subject his immediate and close "attention. But it by no means follows that we concur with Dr. Furnell's view of the special causative relation of impure water to cholera epidemics. The bad water is always there—the cholera not always. Bad water is simply one of the predisposing causes of cholera, but there are others which may be left to do their deadly work when the bad water has been dealt with, and, as an important

contribution to the discussion of this matter, we shall here introduce the following table, with which the Report is concluded :—

Return showing the Deaths from Cholera in the Town of Madras from 1855 to 1884.

Years.	Deaths from Cholera.	Years.	Deaths from Cholera.	
1855	1,956	1870	861	
1856	805	1871	493	
1857	1,378	1872	5	Red Hills water supplied.
1858	1,965	1873	6	
1859	982	1874	—	
1860	2,580	1875	879	Famine years.
1861	2,776	1876	2,035	
1862	3,635	1877	6,246	
1863	1,684	1878	64	
1864	574	1879	34	
1865	944	1880	2	
1866	2,984	1881	126	
1867	514	1882	441	
1868	13	1883	168	
1869	568	1884	269	Up to 31st July, 1884.

47. Taken as a whole, the figures show a large reduction in the cholera mortality since the Red Hills water was brought into Madras. The great increase apparent in the so-called famine years in this table was, however, part of one of the greatest cholera epidemics on record, which extended over a large area of India, and the fatality from cholera in the town itself was due in great part to the influx of a vast number of starving people, and to great increase of all sanitary evils (for these were not dealt with) consequent on the overcrowding. The facts rather would seem to show that, while in former years the predisposition to attacks of cholera was augmented by the use of foul well water, this special cause ceased to operate when the purer water-supply was introduced, but that other unremoved causes were left to become active when epidemic increase came round. It ought to be stated at the same time that the end of 1876 and 1877, and not 1875, constituted the famine period.

48. Considering that Dr. Bidie had only entered on his work, he has drawn up a very instructive and useful Report for the year. It would, of course, have been more satisfactory if he had been able to report a sufficiency of good work, well done, and life saved. It is, at the same time, not too much to state that in Madras, as in other parts of India, the work of disease reporting has been long since completed for all practical purposes, and that what is now required is skilled sanitary action on the information already in our possession. So far as we can judge from the present Report the great desideratum in all municipalities and local fund circles is appreciation of the importance of our present knowledge to the health and prosperity of the people, for it can scarcely be supposed that, if local authorities realized the fact that death and disease rates tell us not only how many people die of epidemics but how many have their working power permanently injured, and with it the means of earning a living for themselves and their families, that the present inaction would continue. We have instanced the case of Guntur, as showing how much can be done by persistent and intelligent use of known and simple sanitary methods at a cost of 9*d.* a head of the population per annum, and the Report shows how much less had been done by the other municipalities by an outlay of a shilling a head.

49. Neither the municipalities nor the local fund circles had even spent the sums allotted to them for public health purposes, and it is most satisfactory to see that the Government has taken up this matter, for in their Resolution on the Report under review they say, "This result is more "disappointing even than that of last year, and the special attention of chairmen of all municipal "councils will now be drawn to the necessity of great attention being paid to the judicious "expenditure of all the municipal sanitary allotments within the year." And referring to the same falling off in local fund circles they continue, "It is very unsatisfactory to observe that the "retrograde movement noticed in the last year's Report has continued. This is due in most cases "not to insufficiency of allotments, but to the allotments made not being sufficiently utilized. "Presidents of all local Boards will now be called on specially to report how far in the current year "they expect to be able to utilize their sanitary allotment, and to give full reasons in cases where "they report that they do not expect to be able to spend all the funds allotted for sanitation."

50. This action of the Presidency Government involves a principle of the greatest importance in sanitary work. India has not yet obtained the advantages of an efficient sanitary administration while professing to do sanitary work. Up to the present time the proceedings may, without detracting from their importance, be considered as mainly tentative, and while powers have been conferred on local authorities, it is necessary that these authorities should realize the fact that power has been conferred, not to be kept, but to be used for the common good. The evidence in the report under review, so far as it goes, is sufficient to show that there need be no fear of the necessary outlay for sanitary work pressing heavily on the towns and villages. What is more required than money is simply energy and effective action, and we hail this step of the Madras Government in calling the local authorities to account as a decided advance towards better administrative arrangements.

10th April, 1886.

No. 3.

MEMORANDUM of the ARMY SANITARY COMMISSION on the REPORT of the SANITARY COMMISSIONER of the GOVERNMENT of BOMBAY for 1884.

1. In conformity with present practice, this Report deals exclusively with the sanitary condition of the Civil population of Bombay Presidency. But at the same time it contains a brief enumeration of sanitary works carried out in the course of the year at military stations.

2. On the 1st July 1884, an important change in the registration arrangements was made, whereby the compilation of vital statistics was vested solely in the Deputy Sanitary Commissioner and his officers, "who is thus brought each month into direct communication with every village in his "district."

We may hope that this arrangement may ensure greater accuracy and despatch in the work of compilation, and, what is of more importance, that it will keep the Sanitary Commissioner fully informed as to the state of the villages, and enable him to give information and advice on any preventive measures required, especially against epedemic diseases within his district. In the advance and improvement of Indian registration considerable delay has taken place in arriving at the facts for practical use, and it may show the importance attached to having immediate information during epidemic seasons in London that during cholera epidemics it was the custom to publish a daily list of cholera deaths, with their residences thus enabling local measures to be at once applied. What has been done in Bombay has thus been a step in the right direction, provided executive measures are made to correspond with it.

3. The registration districts were also re-arranged, and the result so far has been satisfactory. "The new arrangement has been found to work admirably, as the statistics are now received from "the villages with much greater punctuality than formerly." This has been, no doubt, partly due to the fact that the areas of the new districts have been made conterminous with collectorates, in which the same language is spoken. In the western and central districts there are nine collectorates in which the language is Marathi. In the southern district there are four collectorates in which Kanarese is spoken. In eastern Gujarat the language is Gujarati in five collectorates, and there are five collectorates in Sind district where the language is Sindi. The city of Bombay has its own registration arrangements.

4. The entire population of the Presidency from which returns of births and deaths are now received amounted in 1881 to 16,464,414. The birth-rates for a series of years have been as follows:—

Ten years mean.	Rate per 1,000.
1874—1883	22·61
1883	30·50
1884	32·50

There has thus been a considerable increase in the numbers registered, although the latest returns are still below what ought to be the real rate.

Out of 24 collectorates, including Bombay city, the lowest rate, 16·91 per 1,000, in 1884, was returned from Hyderabad, and Bombay city only returned a rate of 18·59 per 1,000. The highest birth-rate of the year was returned from Dharwar. It reached 43·43 per 1,000, which may be contrasted with the registering work done in Bombay, while this, besides falling far below the average rate for the Presidency, is marked by great irregularity in different years. It is probable that none of the rates are absolutely correct, but the tables show that, as a whole, the birth registration is advancing towards accuracy, and that steps ought to be taken to improve registration in Bombay, which is at present the most populous city in India, and one in which registration of births ought to be better done.

The actual numbers of births registered for the entire Presidency in 1884 were:—

Of males	278,986
Of females	255,737
Total births	534,723

5. *Deaths.*—The deaths registered in 1884 were:—

Of males	214,376
Of females	194,033
Total deaths	408,409

equal a rate of 24·82 per 1,000, obviously far below the true rate of a population not only unhealthy, but subject to violent epidemic outbreaks and other death causes, as, for example, the famine experience

of 1877–78, during the first year of which the registered deaths were 627,708, and during the second 532,951. During the last five years the death registration, but not necessarily the mortality, has stood as follows :—

Years.	Registered Deaths.
1880	328,673
1881	381,450
1882	343,418
1883	420,198
1884	408,409

This table only shows that the registration of deaths, like the registration of births, has been improving in the Presidency as a whole, but an examination of the district rates shows that the existing defects are not general. The Sind registration in 1884 only returned an average death-rate of 17·27 per 1,000, while the other districts yielded results much nearer the true rates. The best registered district was the southern, which returned a rate of 31·04 per 1,000, still, however, below the truth. The city of Bombay had a death-rate of 28·82 per 1,000, which is much nearer the truth than its birth-rate. Taking the collectorates separately, the registered death-rates lay between 15·55 per 1,000 for Thar and Parkár, and 35·15 for Broach, marking the relative efficiency of registration in each. Under the new arrangements it is not impossible that these extreme ratios may be more equalised.

6. Under present conditions, of the registered deaths 45·07 per cent. were returned under five years of age. But this is a scarcely reliable ratio, and when compared with the rates at ages above five, it would appear as if the registration were most defective in the higher ages. This is all that the figures warrant us in stating.

7. The death causes, according to the classification in use, were the following :—

Diseases.	Numbers.	Ratio per 1,000 of Population.
Cholera	13,804	·84
Small-pox	14,438	·88
Fever	276,989	16·83
Bowel complaints	35,283	2·19
Injuries	5,570	·34
Other causes	61,625	3·74
All causes	408,409	24·82

This table shows that the least fatal epidemic of 1884 was cholera, and the most fatal fever.

8. *Cholera* prevailed during some part of the year over the whole country, but its incidence was very irregular. In the western districts, including Bombay city, the disease showed itself as a distinct outbreak in the earlier months, to be followed by a partial subsidence in the middle of the year, and then an increase towards the end of the year. In the eastern districts the epidemic existed in force in the middle months of the year. In the central districts the deaths were more scattered, but were most numerous towards the end of the year. In the southern districts the epidemic was severe on and after June, and in the Sind districts there was no cholera till October. In each of the registration divisions the epidemic appeared to follow a special time prevalence, and there was no apparent law of extension or continuity of the epidemic. There are in all 24 separate registration districts, and cholera appeared in greater or less prevalence in all of them; but many of the registration circles in these districts escaped the disease, for out of 283 circles, 157 yielded all the mortality. The village returns exhibited the usual anomalies, for the whole cholera mortality of the year was returned from 1,417 villages out of 24,536 in the Presidency. The towns suffered more proportionally than the villages, for out of 62 there were deaths from cholera returned by 33.

9. We have no means of ascertaining the exact ratio in which cholera prevailed in the attacked villages. These yielded in all 11,684 deaths, or about eight per village. Taken over the whole country population, the cholera death-rate was 0·81 per 1,000. The highest death-rate of the year was 5·27 per 1,000 of population in Dharwar, but it was yielded by 424 villages out of 1,281, so that in this case, at least, the rate would have to be multiplied by three, which would bring it up to 15·82 per 1,000 for the attacked villages. It is very important to the true understanding of the problems to be dealt with that this point should be borne in mind, for it shows that a low general rate may really mean great loss and suffering among a circumscribed population.

In the towns there were 2,120 cholera deaths, or 1·01 per 1,000 of the whole town population; but of these deaths Bombay city yielded 568, and Hubli in Dharwar 466, or about half the whole town mortality between them.

10. The monthly prevalence of cholera was as follows:—

Months.	Cholera Deaths.	Months.	Cholera Deaths.
January	207	July	2,738
February	119	August	2,746
March	414	September	1,665
April	337	October	1,626
May	556	November	1,100
June	1,705	December	556

From the history already given, it will be evident that this table gives the year's facts, but not the monthly epidemic history, because the months of greatest prevalence, June to September, were past before the Sind epidemic took place.

11. In previous memoranda, we have given the annual cholera mortality of Bombay city during a series of years as part of the epidemic history. It is unnecessary to repeat the data at present, but we can place a general statement of the facts for a period of 36 years alongside the sanitary history of the Presidency capital. It happens that these 36 years divide themselves into two classes of 18 years each. The first section comprehends the years 1848 to 1865 inclusive, during which there was little sanitary work done in any part of the Presidency. The second section includes 16 years from 1866 to 1883 inclusive, and contains the years not only of sanitary work, but of increasing registration of deaths, during which a much larger proportion of the mortality has been reported in the city.

During the first series of 18 years there were 40,341 cholera deaths reported, and during the second 18 years the registered cholera deaths have been 9,343. There are, no doubt, errors in both series of numbers, but, on the other hand, cholera is a well known disease among the people, and, making allowance for some error, we have certainly the fact that since sanitary work has been in some sense done, the cholera deaths have fallen to one-fourth part of their previous numbers.

The average deaths in Bombay City for the whole period of 36 years has been 1,380 per annum, and in 1884 its greatly increased population had only 568 deaths from the epidemic, a number still far above what the mortality of the year ought to have been.

12. Taken over the whole Presidency, the cholera mortality of 1884 was 0·84 per 1,000, a shade under the preceding five years' average, which was 0·85 per 1,000.

The deaths actually registered in the same years were:—

1879	6,937	1882	7,904
1880	684	1883	37,954
1881	16,694	1884	13,804

As we have compared the deaths for two series of years from cholera in Bombay city, we may give the results for two series of nine years each for the Presidency as a whole:—

Years.	Deaths from Cholera.
1866 to 1874	111,296
1875 „ 1883	253,840

If the reduction of city deaths to one-fourth may be fairly assumed as marking the progress of sanitary improvement, what conclusion can be drawn from the cholera history of the Presidency, or rather of the country villages, in which the cholera mortality of recent years has considerably more than doubled, except that the localizing influences in the villages have increased in intensity, while those in Bombay city have notably diminished.

13. What these influences are is quite well known, and they have almost ceased to be made subjects of remark in local reports. There are, however, a few facts stated by Mr. Hewlett which may be quoted. The village of Karjat is more frequently affected with cholera than any other part of the Thana collectorate, and the disease clung persistently to it and to a neighbouring one. The reason appears to be a topographical one, and is described as follows:—"The infected portion of Karjat rests "in a valley running irregularly north and south for some seven or eight miles, and varying in "breadth from one to three. The lower ground is fertile and is extensively sown with rice, a crop "requiring much water for its cultivation. The atmosphere is oppressively warm, moist, and still. "Through the valley flows the Dhawali river, a clear bright stream, from which the villages derive "their chief water-supply. Numerous small villages are scattered up and down through the valley; "many of them have suffered severely." Similar conditions are described as existing at Dahivali village of 1,239 inhabitants, among whom where 37 cholera deaths, of which "all but two occurred "among the population inhabiting a low lying row of huts on the western border of the village. The "ground here is damp, whereas the eastern and central parts of the village are raised and consequently "drier." This locality, which is about a fifth part of the village, yielded all the deaths.

The disease in Bettigeri in Dharwar was almost entirely confined to low caste people living in the poorer quarters of the town, on the edge of "the filthy Landy Nala."

In the Bombay city most of the fatal cases take place among people using the city water, a fact which proves that good water *per se* is no protection against cholera. But in 1884 there were groups of cases among people using well water. The officer of health says, that he found in three of the

well waters "organisms of a most suspicious type." A description scarcely sufficient for any etiological purpose.

13. The deaths in Bombay bore so high a ratio to the attacks that the Government ordered an inquiry. The Surgeon-General was of opinion that the attacks were under-estimated, but Mr. Hewlett considers the high mortality due in part, at least, to removal of cases to hospital over long distances. As this view has been called in question in the Government resolution, it may be well to state the principles which ought to regulate removal as these have been determined by past experience.

14. There are diseases, especially epidemic cases, and accidents in which the patient has to struggle for life, and the question whether he may have a better chance of recovery by care on the spot or by removal to a distant hospital depends on the state of the case. The experience of cholera in England during 1848–49 was that the mortality in hospital cases was determined by the distance to which patients had to be moved, and hence the sanitary rule that in certain cases epidemic attacks are treated with least danger to life on the spot, and that it is better for all parties to remove the healthy if necessary; and any way that during epidemics it is safest for the patient, whose interest is the one to be considered in such cases, to have the required hospital accommodation as near his residence as possible. This is not so difficult a matter as at first sight appears, because epidemic localities are well known, they are few in number, and the attack is limited as to time. We shall recur to this matter again.

15. In the absence of local information as to the sanitary state of affected villages, it may, nevertheless, be stated generally that the history of cholera during the last 18 years, already given, shows that this epidemic disease either has increased in intensity, which is scarcely probable, or that the susceptibility of the population to cholera epidemic attacks has increased, and as we know that the local intensity of all epidemics is influenced by local conditions, we arrive at the conclusion that the future safety of the people depends on the extent to which efficient sanitary work is done or neglected to be done. What the rural districts require is an efficient sanitary executive.

16. *Small-pox.*—Bombay Presidency has had an efficient vaccination service for many years, and we should expect to find proof of its preventive agency in the statistics of small-pox mortality. In former memoranda we have discussed this subject, and we shall here introduce the following tabular statement of vaccinations and small-pox deaths, which, as will be seen, contains facts on both sides of the question:—

Years.	Primary Vaccinations.	Small-pox Deaths.	Years.	Primary Vaccinations.	Small-pox Deaths.
1873	—	2,935	1879	561,969	1,155
1874	—	3,903	1880	586,501	940
1875	671,817	3,461	1881	642,505	539
1876	699,639	11,817	1882	229,323	1,690
1877	732,184	27,369	1883	792,206	13,404
1878	670,055	4,475	1884	826,965	14,488
Total	2,754,695	60,960	Total	4,139,469	32,107

At first sight this abstract appears to show a falling off in small-pox mortality to little short of one half during the last six years, but it has to be remembered that the years 1877–78 were the famine and scarcity years, which, in Indian experience, are years of high small-pox mortality; nevertheless, all the years in the second column, except the two last, show a large reduction in the deaths over the years of lower mortality in the first column. But at this point we are met by the fact of increasing small-pox mortality in 1883–84.

If we take the last three years it would seem that an epidemic of small-pox was in progress in the face of the vaccination.

17. The following abstract of monthly deaths shows the facts for 1884:—

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January	1,835	July	812
February	2,211	August	500
March	2,413	September	328
April	2,364	October	260
May	1,856	November	223
June	1,387	December	309

The months of highest mortality were nearly the same over the districts thus affording additional evidence of epidemic prevalence, and this was general, as is shown by the fact that small-pox deaths were registered in all the districts and in 234 out of 283 circles of registration. But the whole mortality took place in 3,072 villages out of 24,536. The disease prevailed in 39 towns out of 62. The town death-rate was 0·58 per 1,000, and the country rate 0·92 per 1,000. The small-pox death-rate for the whole Presidency, which had been 0·21 per 1,000 as the mean of five preceding years, was raised in 1884 to 0·88 per 1,000, or about fourfold.

18. The highest death-rates of the year, lying between 2·82 and 3·10 per 1,000, were returned from the southern registration district, which includes Belgaum, Dharwar, Kaladgi, and Kanara, and it is worthy of remark that this same district returned the highest rates of the year from cholera but not from fever, which, as we shall see, was not an epidemic in 1884. We have already seen that the total deaths from small-pox in 1884 were 14,438. Of these the deaths registered as under one year of age were 3,723, and between one year and 12 years there were 5,423 deaths. Above 12 years of age there were 5,292 deaths registered, thus about two thirds of the years' mortality took place at young ages, and one fourth under one year of age.

19. We shall next trace briefly the relation of small-pox mortality to vaccination in 1884-85. The staff was as follows:—

Deputy Sanitary Commissioners	5
Superintendents of Vaccination	3
Inspectors of Sanitation and Vaccination	31
Assistant Superintendents of Vaccination	5
Clerks and karkuns	29
Vaccinators, all classes	477
Peons	502
Total staff	1,052

Of this staff 152 vaccinators and 158 peons are employed in Native States; so that in discussing the question it must be borne in mind that while the registration of deaths only includes a population of 16,503,663 within British territory, the vaccination service covers not only this population but an additional 9,111,865 in the Native States.

The children born in British territory in 1884 and registered amounted to 534,723, but 97,143 of them died under one year of age, leaving at that age 437,580 available for vaccination.

The actual numbers successfully vaccinated under one year of age were 328,646, and between one and six 155,393. In round numbers, therefore, about three fourths of the children available for vaccination under one year of age were successfully vaccinated in 1884.

20. In the preceding table we have placed side by side the vaccinations and small-pox deaths for a period of 10 years, with the result that, while 6,904,464 primary vaccinations were performed, 79,229 persons died of small-pox, or about one death for every 90 primary operations. But, as already stated, the vaccinations include those done in the Native States, which in the last year of the series amounted to between 90,000 and 100,000.

The conclusion from these years of experience appears to be that, while there is evidence of a large saving of life from vaccination, and no doubt of a corresponding reduction in the results of small-pox attacks which are not fatal, the disease is nevertheless liable to periodical epidemic increase, which can only be met by more active sanitary work in the towns and villages.

21. *Fevers.*—Deaths under this head were returned from all the registration districts, from all the circles of registration, from all the towns, and from 22,441 villages out of 24,536. Fever was thus generally prevalent over the entire Presidency.

22. The following table, abstracted from the Report, shows the monthly fever mortality for a series of years.

Months.	Fever Deaths Registered.		
	Mean of 10 Years, 1874 to 1883.	1883.	1884.
January	22,664	23,513	23,510
February	19,393	21,114	20,290
March	20,540	22,669	22,096
April	19,751	22,885	20,469
May	19,595	20,512	20,673
June	18,259	20,700	19,498
July	20,944	23,106	18,902
August	23,543	26,703	22,273
September	23,133	30,755	23,462
October	23,697	29,144	27,767
November	23,745	26,587	31,512
December	25,207	25,153	28,537
Total	263,385	296,741	276,989

These facts show clearly that the deaths registered under the head of fevers are on the increase. The fever-rate for the whole Presidency in 1884 was 16·83 per 1,000, and for the previous five years it was 16·09 per 1,000. The rates in 1884 varied between 8·06 per 1,000, the lowest rate, in Ratnagiri district, and 28·72 per 1,000 in Broach, which was the highest. The town fever-rates varied much more than the country rates. They ranked between 3·99 per 1,000 in Kaladgi town, and 42·60 per 1,000 in Virangam, where, out of 18,990 people, 809 died of fever.

The general town fever death-rate was 13·83 per 1,000, and the rate for the districts 17·27 per 1,000, and, as already stated, the Presidency rate was 16·83 per 1,000.

The information about fevers is confined to the year's statistics, and does not include local causes.

23. *Bowel complaints*, chiefly diarrhœa and dysentery, yielded a death-rate of 2·19 per 1,000 for the towns and districts, and of course the same rate prevailed over the Presidency in 1884. The previous five years' rate was 1·77 per 1,000. The deaths under this head were 35,983. They were returned from all the districts, from 273 out of 283 registration circles, and from 7,140 villages out of 24,536. The attacks were most fatal in the latter months of the year, as the following abstract shows :—

Months.	Bowel Complaint Deaths.	Months.	Bowel Complaint Deaths.
January	2,728	July	2,938
February	2,149	August	3,823
March	2,821	September	3,849
April	2,409	October	3,732
May	2,569	November	3,530
June	2,556	December	3,384

By comparing this table with a preceding one showing the monthly mortality from cholera, it will be found that there is a correspondence in the periods of increase of both diseases. The bowel complaints appear to have increased at the same period as the cholera, but the augmentation does not appear to have assumed the epidemic character. It was general over most of the province, but Sind suffered least. During the six years following 1872 the annual mean mortality from these diseases was 37,091 deaths, and during the next six years, ending 1884, the mean has been 30,128 deaths, showing a large reduction in the rate. It is worthy of remark that the same districts which suffered most from cholera, Belgaum and Dharwar, were those which yielded the highest death-rates from bowel complaints, namely, 5·43 and 5·23 per 1,000.

24. *Injuries.*—There were 5,570 deaths from these causes in 1884, of which 3,231 were of males and 2,339 of females.

These are classed as follows :—

Drowning	2,461
Poisoning	121
Hanging	213
Wounding	415
Wild beasts	118
Snake-bite	1,077
Others	1,165
	5,570

Of the drownings there were 308 suicides in wells and 38 in tanks. There were 906 accidents in wells and 320 in tanks. Other drownings in wells were 55 and in tanks 76. Hence, of the drownings 1,203 took place in sources of domestic water-supply. From snake-bites the mean mortality of five years was 1,185, and it is so far satisfactory to see that the deaths from this cause in 1884 has been the smallest since 1879. The months when snake-bites are most fatal are June to October inclusive, marking the time when personal care is most necessary and the destruction of snakes should be most active.

25. *Other causes.*—Deaths, of which the causes are unascertained, were 61,625, and these call for no remark.

26. *Sanitary Works* (*Military*).—The total expenditure under this head in 1884 was in round numbers 9,888*l*. Of this amount, 3,459*l*. were spent for a hospital for British troops at Ahmedabad, and 1,438*l*. at Nasirabad on the new water-supply works. The remainder was laid out on minor improvements at 19 other stations. The only remarks called for on this section of the Report are the smallness of the sum devoted to sanitary work, and the absence of any special allotments for removing well known disease causes at the more unhealthy stations.

27. *Sanitary Works* (*Civil*).—Excluding the city of Bombay, there are 164 undrained municipal towns in the province, having an aggregate population of 1,910,405. Their total income in 1884 was 308,672*l*. out of which 66,140*l*. were spent on conservancy, or about 8¼*d*. per head. In drained towns in England, in which the household sewage is removed by sewers to an outlet, the average cost of scavenging is about 1*s*. per head. In Indian towns, the conservancy arrangements include removal of house sewage by hand, or at least ought to do so. No important permanent works appear to have been undertaken in the course of the year. Most of the reports show that matters of current sanitary detail, such as surface drainage, well improvements, and surface cleanliness, were more or less attended to, but cesspools appear to be in general use in the municipal towns, and so long as this is the case none of them can be safe during epidemic times. Public latrines are coming into

more general use, and wherever there is sufficient provision of this kind, house cesspools ought to be cleansed and filled up. Dust bins have been put up in a number of these towns. In a number of instances water distribution has been extended and improved by tanks, stand pipes, &c. As will have been seen, the work of 1884 has been mainly directed to current sanitary measures, and there is no evidence in the abstracts to show that any great advances have been made. This result is also shown by the statistics from which we learn that the death-rate during 1884 in 62 towns was 29·25 per 1,000, against a previous five years' average of 29·24. All we can do on the information before us is to urge more active proceedings in the directions laid down in our "Suggestions," but especially would we advise, as one of the lessons taught by epidemics in these small towns, that no time should be lost in cleansing and abolishing every cesspool in them. Whatever method may be adopted in removing house sewage, these plague spots in houses, villages, and towns should be dealt with at once.

28. *Local Fund Circles.*—The sanitary work in these circles was mainly the providing and repair of wells, on which about 13,000*l.* were spent in the course of the year. The amount is of course very small when we compare it with the wants of many millions of the country population, but we desire to express satisfaction with this important advance in sanitary improvement so far as it has gone.

29. *Personal Proceedings* and *General Remarks.*—This, which constitutes Sect. X. of Mr. Hewlett's Report, is mainly devoted to a discussion of practical points of cholera history, during which he has brought together a large amount of experience to show that, whatever may be the cause of cholera, there is no proof that the disease is communicable from person to person. The subject is not a new one, but as there is still a tendency to revert to former views on the subject, it is necessary for the present time at least to reiterate the facts. This is the course we ourselves have adopted, for no authority of opinion as against opinion can decide such controversies, and besides it is no part of our duty to throw any influence except that derived from facts either on one side or the other.

If any carefully made observations showing that cholera is communicable can be adduced, we should of course give them all due weight, but, in place of any such, the appeal has usually been made (as in the present case, of presumed danger from a proposed cholera hospital on account of proximity) not to experience but to some one's personal opinion, on which, of course, no steps can be taken nor money spent.

30. We shall next notice certain results which have followed from the appointment by Government of a full time medical officer to inspect passengers and crews of incoming and outgoing vessels at Bombay, with the object of removing cases of sickness and treating them on shore. The officer entered on his duty on 10th August 1884, and by the end of the year he had inspected the following number of outgoing vessels:—

		Crews and Passengers.
Square rigged and steamers	163	16,309
Native craft	74	1,613
Pilgrim ships	9	7,390
	246	25,312

This experience has an important bearing on quarantine. Of the ships 114, having on board 1,732 passengers and 7,931 of crews, sailed for Europe *vid* the Suez Canal, and all were found healthy. The only diseases found on board any of the ships in this list were some cases of measles among children on board one of the pilgrim vessels which were landed, and the vessel was disinfected before sailing.

Particulars regarding incoming vessels are only given respecting those which had arrived with disease on board. Eleven such ships are enumerated as coming from foreign ports, including troopships. Their crews numbered 1,685, and their passengers 9,363. There were found on board seven cases of small-pox and 15 cases of measles, and it is worthy of remark that all these cases were found on ships which had come from Port Said and other Red Sea ports.

We have seen that the pilgrim ships cleared from Bombay after the removal of a few cases of measles, which took place among children on board one of them. But it was otherwise with the return pilgrim ships. Between the 28th October and 18th December, there arrived at Bombay ten pilgrim ships, having on board 5,303 pilgrims, from among whom there were 303 admissions to hospital, and 41 of them died. But only one pilgrim ship was placed in temporary quarantine from having five cases of small-pox on board. Of country craft, there arrived 121 from Persian ports, having 2,818 of crews and passengers on board, and 48 with 1,079 on board from other foreign ports, and none of the vessels had any infectious disease on board.

31. This experience is, of course, too limited to enable general rules to be deduced from it, but it is evident that if any danger of disease importation existed, it was incurred, not by any foreign ports, but by Bombay itself. And as we must suppose that all arrivals at Bombay left their several ports free of disease, the cases found on arrival by the Officer of Health must have become developed on the voyages, and hence the justifiable conclusion that the state of the ships is of as much importance to the results of the voyages as the state of health of the crews on departure.

32. As bearing on the same subject, it ought to be stated that in the course of the year there were 51 cases of cholera among the harbour population of Bombay, of which no fewer than 43 died. It

was this enormous mortality to which we have referred in a preceding paragraph as having in all probability been due to removal of cases from vessels to the shore and thence to a distant hospital. It may be considered certain that a cholera death-rate of 84 per cent. of the attacks is due to something else besides the disease. We would suggest whether some temporary accommodation, such as a tent near at hand, would not yield less unfavourable results.

So far as these harbour cases have a bearing on the question of quarantine against Bombay, it is in the highest degree probable that they owed their origin solely to the foul condition of the foreshores, as pointed out both by the Sanitary Commissioner and officer of health. There are port trustees who it appears have powers to prevent shore nuisances, and surely no argument ought to be required to show that by providing for the cleansing and keeping clean the foreshores, they would at the same time be invalidating one of the arguments used for enforcing quarantine against arrivals from Indian ports.

33. There is one point in which the port practice is deficient. We have seen that inspection of passengers and crews is now in use. No doubt this step is necessary, apart from any doctrinal reasons, but suppose the ship itself is a disease locality, it is clear that no amount of shore inspection of passengers will prevent the appearance of disease at sea, and quarantine might follow in spite of inspection.

The effectual substitution of ship hygiene for quarantine on arrival depends not on the health of crew and passengers at the port of departure, but on the sanitary condition and subsequent sanitary management of the ship during the voyage. The duty no doubt devolves on the captains and owners, but surely the port authorities at Bombay ought to have power to prevent careless captains from endangering the vast commerce of their city. In fact, this matter of protecting the health of ships from epidemic diseases is the only logical remedy against quarantine, and we agree with the Sanitary Commissioner that there should be power lodged somewhere to ensure that necessary measures are enforced on board ship, just as the town Commissioners are empowered to deal with unwholesome houses on shore.

This principle had the sanction of the first General Board of Health in England, and it was affirmed by the International Quarantine Conference of Paris in 1851-52. Moreover, it is in accordance with the dictates of common sense and sound reason, and it would enable clean bills of health to be more satisfactorily issued.*

34. A very important step has been taken by the Government of Bombay in the appointment of a Sanitary Engineer for the Presidency, whose services for consultation will be placed at the disposal of the local authorities. Mr. Hewlett justifies the appointment on the ground of past engineering mistakes, which he can "only term hideous." There have been many such errors detailed in past Indian reports, and they have all arisen as similar mistakes in architecture have arisen, from failing to recognize that the sanitary details of engineering and architectural works lie outside the technical details of common planning and construction. Mr. Hewlett gives an illustrative case of the Government house at Ghanesh Khind, where works of house drainage were planned and executed to remove liquid sewage, which they no doubt did, but from overlooking the sanitary element in the works, foul sewer gas was allowed to diffuse itself over the whole building. Again, there are many cases in which bathing arrangements of buildings of what may be called good architectural design have been such as to diffuse damp under inhabited rooms.

35. Another most important element in all sanitary construction is economy. Anything can be done with money at command, and most of the mistakes in sanitary as well as in architectural works have in reality cost very much more than perfectly efficient works would have done in the hands of a competent sanitary engineer or architect. Architectural effect has nothing to do with a wholesome barrack, hospital, or house. If money is no object, any amount may of course be expended in adding the architectural element. But it may be safely affirmed that the drainage works and architectural designs on which most money has been spent have not been the most healthy.

36. The sanitary rule for India as regards drainage works is that the rainfall should be removed by surface drains and a well formed surface, and that built sewers or drains for house purposes are unnecessary, for pipe drains laid down on the principles in our "Suggestions" will in the majority of cases be sufficient.

37. As regards barracks and hospitals everywhere, the plans should be based solely on the sanitary requirements for the healthy and for the sick, as these have been determined by experience, and not by theory or fancy, and, after the sanitary element has been provided for, the less money spent the better, and this rule is the more necessary in warm climates, because after a certain term of use hospitals are very apt to become unhealthy, and require to be rebuilt or evacuated for part of every year.

38. Again, a very important object to be attained by the appointment of a Presidency Sanitary Engineer is the discovery and removal of local disease causes at stations, towns, and villages, and in this part of the work he should be associated with the Sanitary Commissioner or Sanitary Officer in the manner laid down in Section V. of our "Suggestions," to which we must refer for the details. If the services of this new officer are made use of for improving the more defective stations, as well as for the municipal towns, several of which we are glad to learn have already availed themselves of his services, we have no doubt that much public good will follow.

*We have reason to believe that, since Mr. Hewlett's Report was sent in, ship inspection has been authorised, and, if so, it will turn out to be of great value to commerce.

39. Mr. Hewlett resumés the cholera discussion on the proper site for a cholera hospital in the fort of Bombay, to which we have already referred, a proposed site having been objected to on the assumed ground of the infectious nature of cholera cases. It is unnecessary for us to enter further into the question, for we have already dealt with the only important element in it, so far as the sick are concerned, and this is that hospital accommodation for cholera cases should be provided as near as possible to the points where such accommodation is required.

40. One of the most hopeful statements in the present Report is the contemplated legislation for the sanitary improvement of villages. Many years have passed since we called attention to this subject. We then pointed out that to the peculiar distribution of the Indian population, not in large cities but in scattered villages, was due both the difficulties and facilities of Indian sanitary improvements; that, while no Government could administer the staff or find the funds necessary for so vast a work, it might all be done in a week if the problem were attacked in detail, village by village, and every village by itself. Hence the absolute necessity of an efficient village organization to do the work. The measures required are neither difficult of execution nor expensive in their nature, and nevertheless, from long neglect of them, the people appear to be more liable to epidemics than they were in former times, and, as one well-known result, their death-rates are not only very high, especially from epidemics, but, as another well-known result of this susceptibility, the general stamina and working power of the people is greatly deteriorated, and their means of living reduced below the healthy standard, and this in one of the richest and naturally most productive countries in the world.

It has happened quite recently, indeed, that one perfectly mitigable or removable disease, paroxysmal fever, had so prostrated the working population that rich crops were left to rot on the ground because there were no hands to reap them. We pointed out at the time that here was the point where protecting the health of the working population was one of direct pecuniary interest to the Government, because, not only was there a primary loss of production, but this loss diminished the food of the people, and so lowered their working power and rendered them at the same time more liable to future attacks of disease. The causes of these great losses differ in different districts of India, but they are quite well known, and are all mitigable or removable.

41. So far as we know, the Government of Bombay has been the first to take up this most important subject, and, if these village organisations can be induced to do the work, it will have had the satisfaction of having solved the great Indian epidemic question, the outskirts of which have been as yet barely touched. Of course, some kind of current inspection and advising by the Sanitary Commissioner and his officers (who would be in direct communication with him, as they are elsewhere in India, on all purely sanitary questions) would be required, to secure uniformity, so that one village which was doing its duty was not injured by the neglect of its neighbours.

Precautions of this class are necessary everywhere, and there will, no doubt, be cases in which the advice of the new Sanitary Engineer will save both life and money.

42. There are a few points towards the end of the Report which may be noticed with approval, such as the projected Tansa extension of the Bombay water-supply, the sanitary improvement of manufacturing establishments, and the opening of a leper asylum, by the exertions of the Roman Catholic Bishop, which we agree with the Sanitary Commissioner as likely to be "of the greatest "service in affording proper shelter for the unfortunate lepers in Bombay." It is most satisfactory, also, to be informed that the night-soil of Bombay is now sent through the main sewer to Love Grove, so that the harbour has been at last freed from this great nuisance.

43. Mr. Hewlett concludes his report with a well-merited commendation of the work of his sanitary officers, but in the course of the year only four villages and 102 other places could be inspected.

In conclusion, the present Report contains a large amount of very useful information, but there appears to have been little to report about work actually done. There is, however, a better prospect for the future, if the villages 25,536 in number, are taken in hand.

4th March 1886.

No. 4.

Memorandum of the Army Sanitary Commission on the Report of the Sanitary Commissioner for Bengal for 1884.

1. The population adopted in calculating the statistical ratios for 1884 in this Report is that of the 1881 census, which was returned as 66,163,884, inhabiting an area of 144,863 square miles, at the rate of 456·73 persons per square mile.

2. There are 45 rural districts, containing a population of 63,705,518, occupying 227,615 villages. And 96 towns, whose conjoint population was 2,458,366 in 1881, and it is easy to see from these facts in what direction the sanitary improvement of the vast population of Bengal has to be advanced.

3. The registration of births is still confined to selected towns, 47 in number, situated in 20 districts. In these towns there were registered 39,640 births in 1884, yielding a ratio of 23·51 per 1,000 on the town population, but this rate was made up of rates varying for individual towns between 8·27 and 35·17 per 1,000. The mean rate is, of course, considerably below the truth, but the highest rate is not far from it. The birth returns, such as they are, showed 116 male births for every 100 females, but this average was made up of ratios lying between 98 and 214, so that, even in the selected towns, the birth registration, although showing signs of improvement, is not reliable.

4. Registration of deaths is carried out in all the towns and in 646 circles of registration included within the districts. The deaths from all causes in the districts numbered 1,317,167, yielding a rate of 20·58 per 1,000, against a previous five years' mean of 16·82 per 1,000. In the towns the deaths registered were 67,443 in number, showing a death-rate of 27·43 per 1,000, about 2 per 1,000 under the five years' mean, which was 29·44.

5. For the whole province the registered deaths in 1884 were 1,378,610, equal to 20·83 per 1,000, while the previous five years' mean was 17·39 per 1,000. The registered death-rates showed great diversities in different districts and towns. The extreme rates in the former were 10·59 in Durbhanga and 40·42 in Nuddea. The town rates showed even greater anomalies. The highest rate, 49·07, was reported from Gya, against a previous five years' average of 45·98, while at the other extreme we have Shambazar returning, according to the table, 1·90 per 1,000 (which ought to be 21·90), and Brahmanbarjah a rate of 2·40 (which ought to be 22·40). These, however, are merely typographical mistakes, as the data are all given. But the really lowest rate of the year was 10·63 from Dinapore, against a previous five years' mean of 10·86, showing that the registration in this town of 52,225 people requires looking after.

6. Taking the year's results as a whole, they show that considerable progress is being made with the important work of registration of deaths. The Government is quite alive to the importance of the work, and may be safely left to do the best that can be done with it.

7. Taking the year's facts as a whole, they show that in the towns registering births there were recorded the births of 21,331 males and 18,309 females, and that of the total year's deaths 749,113 were males and 629,497 females.

8. It is not necessary for us to discuss the details of registration at present. The Sanitary Commissioner has entered as fully into these as the data admit, and it is right that he should do so, because the result is that errors are constantly being exposed, which is a necessary proceeding on the way to accuracy. What we have to deal with are the general results of the year's ratios, and the relation of these to sanitary work, which we shall next proceed to discuss, beginning with the chief death causes of 1884, which were as follow:—

Death Causes.	Deaths.	Deaths per 1,000 of Population.
Cholera	134,421	2·03
Small-pox	18,533	·28
Fever	946,233	14·30
Bowel complaints	58,376	·88
Injuries	24,674	·37
All other causes	176,373	2·66
All causes	1,378,610	20·83

9. Taking these death causes in order, we find that the year 1884 was a severe epidemic year for cholera, as will be seen by comparing the annual registered deaths from this disease during the last ten years:—

Years.	Registered Cholera Deaths.
1875	109,988
1876	196,590
1877	155,305
1878	96,192
1879	136,363
1880	39,643
1881	79,180
1882	182,352
1883	90,439
1884	134,421

Epidemic cholera in Bengal is always there, and although the mortality, as the figures show, is subject to fluctuation in different years and groups of years, the tendency shown to so large an increase in 1884, it is to be feared, goes to prove that Bengal cholera, so far at least as the civil population is concerned, has not been rendered less prevalent and fatal by any sanitary measures which have been as yet carried out to cope with it.

10. We shall first deal with the year's facts as they are given in the Report, and then we propose to give some account of the very interesting year's history as this has been collected by the Sanitary Commissioner. In 1884 cholera prevailed in all the rural districts, and in 92 out of 96 towns in Bengal. Deaths from it were registered in 608 circles of registration out of 649 in the province, and, following the usual law of distribution, it attacked 24,621 villages out of 227,615, so that the year's mortality was returned by about a tenth of the population groups or thereabouts, and the rate would be about 5½ deaths per attacked village.

11. The district population, which numbered at the last census 63,705,518, registered 125,031 cholera deaths, or 1·96 per 1,000, and the town population (exclusive of Calcutta) registered 9,390 deaths, or 3·81 per 1,000 on its population of 2,458,366. The conjoint rate for the whole province was 2·03 per 1,000.

12. Every month of 1884 yielded its quota of deaths, and, although the disease appeared later in some districts than in others, the epidemic partook of the nature of a continuous stream passing over from the preceding year, a character well shown in the next abstract, which includes the monthly facts for 1883 and 1884.

Months.	Cholera Deaths.		Rainfall, 1884.
	1883.	1884.	
			Inches.
January	10,675	4,633	·05
February	4,709	3,731	·79
March	6,727	10,557	·83
April	12,691	30,785	2·63
May	13,187	20,124	6·06
June	11,389	9,884	12·04
July	8,935	7,193	11·27
August	6,994	7,179	9·33
September	2,633	3,780	8·91
October	2,289	5,530	6·08
November	3,725	15,993	·53
December	8,139	15,522	·04

As will be seen, there was a large increase of mortality in the last three months of 1884, showing that the epidemic of that year was passing onwards to 1885. The disease did not appear simultaneously in all the districts. Thus, in the four districts in Chota Nagpore there was no cholera in January, two districts only yielded deaths in February, and three in March. In Patna division two districts only out of seven suffered in January, one in February, and four in March. On the other hand, cholera was very severe in the four districts of Dacca division during the whole year. The same history was supplied by the great pilgrimage districts in Orissa division, and, with a single exception, the epidemic was fatal in all the districts of Burdwan and the Presidency division throughout the year. The districts, Cuttack, Poori, and Balasore, in Orissa division, yielded death-rates of 4·16, 3·52, and 7·79 per 1,000, the last having been the highest rate of the year.

13. But the district death-rates were only averages, and did not represent the real severity of cholera in the population groups which suffered. This is what usually happens, but a few examples may be here introduced, because of the practical sanitary questions raised by them. The cholera death-rate in Hughli district was 1·35 per 1,000, but Serampore town, in Hughli, yielded a ratio of 8·30 per 1,000, and in Uterparah circle it was 6·53 per 1,000. In this district the death-rate was very nearly the same in 1883 and 1884, although the per-centage of villages attacked in the former year was 9·43, and in the latter 13·18. The epidemic of 1884 was locally the less severe, but it

covered a third more area. With some exceptions this peculiarity presented itself more or less generally.

In Nuddea district the average rate, 5·79 per 1,000, was very high, but several of the local rates exceeded this amount, and Gangni Thana had a cholera death-rate of 17·27 per 1,000. In Nuddea no fewer than 40·72 per cent. of the villages suffered.

In Murshidabad district, 22·35 per cent. of the villages suffered and yielded a cholera-rate of 4·99 per 1,000, which rate included 10·68 per 1,000 in Goas Thana and 15·17 per 1,000 in Jelingh Thana.

The death-rate of Rajshahye district was 4·95 per 1,000, but this rate included 14·45 per 1,000 for Beauleah town, and 13·74 per 1,000 for Lalpur Thana.

These examples, selected from the Report, appear to be sufficient to show that cholera in the endemic area of Bengal presents the same characteristics as it does elsewhere in India, and the facts all appear to point to the same conclusion, that cholera may cover a large area of country without the death-rate corresponding to the area, while very high rates mostly occur within limited areas. It follows that, given the extent of country covered by any epidemic, the total mortality will depend more on the severity of the epidemic locally than on the extent of area, and hence the sanitary conclusion that diminution of cholera must be sought in dealing with the disease locally.

14. We shall next discuss the information in the Report on the general and local causes of cholera mortality in 1884, beginning with the rainfall, which we have placed in the preceding table opposite the monthly cholera deaths for 1884.

These data show clearly that, as the season advanced and the temperature rose, with little rain, cholera mortality increased, and when rain fell in quantity the deaths rapidly declined, and that when the rainy season had spent itself the death-rate began to rise, and reached a threefold amount at the end of the year, when the rain had practically ceased. As the great fall in the death-rates took place in the less healthy months of the year, and as these months followed and included the months of great increase of rain, we are warranted in concluding that the cleansing and water purifying effect of rain had entered as an important sanitary factor in the result, and hence the year's facts range themselves as evidence of the great importance of continuous cleansing and provision of pure water for local protection against cholera during epidemic seasons.

15. Although much less stress is laid in the present Report on personal intercourse as an agency in spreading cholera, there are still a few cases taken from the local reports which may be noticed.

We shall first give a case mentioned by a native medical officer, merely to point out where the evidence is defective. This officer "refers the causation of the disease to inter-river communication "of the affected villages with contiguous localities where the disease was present, and to contaminated "water-supply . . . . A woman had gone across the river Mohanunda to village Ashapore, in "Maldah, where the disease was raging, to nurse her cholera-stricken grandchild. The child died. "On her return with her clothes soiled by cholera excreta, &c. of her grandchild, her husband was "attacked, and the disease spread into the neighbouring houses, which were close to the river. It "was ascertained that soiled clothes, &c. were washed in the river, and that its water was used for "all purposes."

It will be observed that no dates are given either of the supposed importation or of the two attacks which were supposed to be related to each other. Again, the woman appears to have escaped. Next, the supposed causation is based on a theory that cholera excreta have some specific power of conveying cholera, while we now know that their supposed active germ, the bacillus, has been injected into thousands of persons under the skin in Spain without result. The cholera tainted water theory has never been proved. Besides these defects in the theory, we have the statistical facts that cholera was present in Dinagepore, where the supposed importation took place, and in Rajshahye, Rungpore, Bogra, and Pubna, forming the entire south part of Rajshahye division, for every month of 1884 except in one, and that the divisional deaths amounted to 14,084 in 2,205 attacked villages. In Dinagepore itself 146 attacked villages yielded 481 deaths. It is not necessary, in face of these statistical facts, to assume the presence of a specific germ or its importation, and the result shows that it is not safe to base our views in these matters on preconceived theories, which may land us on mere coincidences instead of proofs, while, as in the present case, they may leave us without any information as to the sanitary surroundings of the people who suffered, or of the means of improving them and saving life in future.

16. Another instance of importation, or rather other instances, are adduced by the native assistant in Noakalf district, in Chittagong division, as follows:—In certain villages in Chhagulnaia Thana, "importation of the disease was distinctly traceable in every village where the disease appeared," and here is the proof,—"Men from several villages went to collect thatching grass from the hill sides "belonging to the Maharajah, and there many of them contracted the disease and some died, and "many of them who returned apparently well were infected with the poison. The first house "in the village where cholera broke out was invariably the house to which a sick or infected man "returned, or the body of a cholera patient was carried. Generally, the largest number of deaths "from the disease occurred only in the families wherein the seed of the disease was introduced "directly from the infected hills." The disease, "when it first made its appearance, did not show "a tendency to spread widely; in a village scarcely more than two houses contracted the malady "from the one where it first showed itself. A house in each village formed a distinct centre, where "the disease was originally carried by importation. Haripur is a big village. The main road from "the subdivision to Chhagulnaia divides into two parts. The part of the village on the northern "side of the road where there was no introduction of the seed of cholera by importation remained

"perfectly free from the disease, whereas that portion of it on the southern side, where a person "returned from the infected place, suffered from the malady."

This case has been given in detail because it is one of the most fully reported importation cases, which have been hitherto adduced from India. It will be observed that no dates are given for any of the events, and no account is taken of what cholera was doing in the district at the same time, because the reporter had no means of knowing. He has pieced together a number of separate events and connected them by speculative matter so as to present a case of importation, which, in the absence of more complete explanation, was perhaps the next best thing he could have done to letting the matter alone. Besides this, the facts of locality are given, and we shall now class them all together.

17. Noakali district, where the events took place, contains 10 circles of registration, in every one of which cholera prevailed. It also contains 2,471 villages, of which 334 returned cholera deaths. There were altogether 1,374 fatal cases of the epidemic, and it covered the district during every month of the year. It will be observed from the history already given that the men first attacked were at work in the open country where the facts show that the epidemic prevailed. They returned to their villages, and what the state of these villages was is faithfully described, and, in fact, this constitutes the true key both to the cholera predisposition and to the required means of prevention. "The above localities are in a very unsanitary condition. The water-supply is bad, several of the "deep tanks being in a foul state from ingrowth of rotten vegetation. Putrid cowdung is heaped "up near dwelling-houses. The dead are buried on the banks of the drinking water tanks." And by way of contrast it is stated that, "Naokali jail, with its superior sanitary arrangements, enjoyed "perfect immunity, although surrounded by the disease."

In this same district there was a severe outbreak in Sudharam town, yielding a death-rate of 4·29 per 1,000. It was confined to Hindus in localities "where the houses were damp and their "surroundings filthy, and the neighbouring drains were offensive and contained in many places "stagnant and foul water."

18. The next case is one of more importance, as it relates to the importation and spread of cholera by pilgrims from Poori, and is thus stated by the Civil Medical Officer, "There is a sameness so "recurring that whatever the theories may be of its causation, whether induced by the impurity "of drinking water, solar or atmospheric conditions, &c., there is little room for doubt as to its "communicability and dissemination by human agency, also that it impresses most where persons "congregate most, and this the large halting grounds in this district bring out pretty clearly, cholera "making its march on and its retreat from these with great distinctness; Khorda Pipli (Satyabadi) "and Poori town, as the centres on which the pilgrim streams converge, suffering the most." The unproved part of this view is that cholera is communicable from person to person. The other parts of it are matters of experience. The distinction is of importance, because on maintaining it depends our adopting rational methods of dealing with the disease. But, as the question has been again raised in the present Report, we may point out that some time ago we gave, in one of our Memoranda, an account of an analysis of causes of death on pilgrim routes, which showed that only a small minority of the deaths, in that instance at least, arose from cholera. We adduced the case to show the need of careful inquiry, so that the exact relation of pilgrimages, not to general mortality, but to mortality from cholera, should be ascertained. The same inquiry showed that the deaths at Poori were by no means all due to cholera. But it may be safely held that crowding along pilgrim routes and at shrines with their sanitary defects, even if no such a disease as epidemic cholera existed, would be attended by a large mortality, and still more is this likely to be the case with a virulent epidemic disease. So far as we know, the real elements of danger are the present deplorable local insanitary conditions, the unhealthy state of pilgrims crowding in successive batches along the routes, excitement, defective or bad food and bad water. Wherever these conditions are found in pilgrim bands or in villages into which they crowd there increase of cholera may be expected. But cholera must also be present in the country, as it was during every month in 1884 over the whole of Orissa, where 17,983 people died of it. The disease was returned from all the registration circles, but it was present in no more than 4,236 villages out of 20,306, a large per-centage no doubt, but nevertheless, in this chief pilgrim region, where bodies of pilgrims moving to and from the shrines must have passed through many villages, the proportion of villages attacked fell far short of that in Nudden, far away from Orissa, where nearly half of all the villages suffered. The evidence of fact, apart from hypothesis, may be accepted as proving that, under existing conditions, crowding of foul localities by pilgrim bodies may increase cholera mortality, but there is no proof that this cholera is all due to, or indeed that any part of it is due to, any form of cholera germ or specific cause. The Sanitary Commissioner, after carefully examining the whole history, concludes as follows:—"I am "not prepared to uphold the view that cholera is dispersed throughout Orissa entirely by foreign "pilgrims and inhabitants of the districts who largely frequent the different temples at times of "festivals, yet there is shown above such correspondence of disease with periods of festivals that this "view cannot easily be set aside, and it must be remembered that this tends to explain the great rise "of the disease in June and July, a time of comparative immunity from cholera in Bengal."

The practical conclusion from the whole discussion on the public health side is hence, that if the evil influence of the pilgrim element, with its fatigue, filth, crowding, and starvation, could be put a stop to there would be less cholera, but if it is to continue the only safety from its effects must be sought in thorough improvement of the sanitary state of the villages and routes.

19. In other districts of Bengal there was little cholera at fairs in cases where ordinary sanitary precautions were taken. The exact statistics of these fairs are not given in the Report, but we may

quote from it the following general statement:—"Of the very large number of fairs held in the "districts, outbreaks of cholera occurred only in the following." Four affected fairs only are mentioned, and we may give the facts for the sake of comparison with the Orissa pilgrim cases. "In "city *Murshidabád*, during the Moharrum, when about 10,000 people were assembled, cholera broke "out and caused about 100 deaths. All sanitary precautions appear to have been taken. The "magistrate believes that this outbreak is referable to the effect of dissipation and bad food." We can connect this outbreak with the prevailing epidemic as follows. Cholera was present in Murshidabad district during every month of 1884 except September, and 6,128 people died of it, showing a death-rate of 4·99 per 1,000, against a previous five years' mean of 1·48 per 1,000. In the city the cholera death-rate was 5·42 per 1,000, showing that both in city and district the disease prevailed in considerable intensity. No wonder if "dissipation and bad food," with the other concomitants, gave rise to an outbreak.

At *Mongalbund* fair, in Dacca, 95,000 people were present, among whom there were two cases of cholera and eight of choleraic diarrhœa. There was no death, and the people dispersed at once. No sanitary details are given. Cholera was present every month in Dacca district, and yielded a death-rate of 3·85 per 1,000, against a previous five years' rate of 1·62 per 1,000.

In the same district another fair, held at *Munshigunge*, yielded four deaths from cholera out of five cases. This fair lasted six weeks, and was attended by 3,282 persons daily, or 144,443 in all. There were 12,177 boats on the river. "The sanitary precautions adopted were all that could be desired."

"At a mela held in *Cuttack* six persons died of cholera; no special sanitary precautions had been taken." Cuttack is one of the Orissa pilgrim districts, and yielded a death-rate from cholera of 4·16 per 1,000, against a previous five years' mean of 2·53 per 1,000.

20. The experience of these fairs may be thus summed up. Of the "very large number of fairs" held in Bengal, all escaped cholera except four. At one of these there were no fatal cases. At the other three there were 110 deaths, but 100 of these took place, as stated, at Murshidabad, not at a fair properly so called, and in the districts where these assemblies were held, cholera reigned with a nearly twofold mortality. The result of this year's experience is that, with ordinary sanitary care, there is little risk of cholera at fairs.

21. The local causes of epidemic outbreaks in Bengal are so well known that it is scarcely necessary to refer to them. But as we have already cited one or two local cases, we may add the following. Referring to alleged importation of cholera into unhealthy localities by pilgrims, the Sanitary Commissioner makes the following remarks as the result of inquiries:—"The fact is that, when cholera, "engendered by causes not yet definitely determined, and fostered by climatic influences or local "insanitary conditions, is prevailing in any locality, pilgrims, if present there, suffer in common with "the local residents, often more severely, owing to fatigue, old age, debility, bad food or water, &c., "but they do not impart or communicate the disease." And he gives examples of from fivefold to tenfold mortality in villages not traversed by pilgrims over the death-rates in villages through which they had passed.

22. In *Midnapore* town, the cholera death-rate of which was 5·89 per 1,000, people who were "indifferent regarding their water-supply, which was bad, and whose surroundings were most "objectionable in a sanitary point of view, suffered most, while those who were most particular in "these matters escaped."

23. A very fatal outbreak took place in bustees of coolies at the jute mills of *Rishra* and *Mohesh*, in Hughli, "which are attacked annually." There were 214 attacks among them, and 118 died. "The bustees are densely crowded, are in an insanitary condition, and the habits of the people "residing in them are filthy."

It is an important fact in cholera history that these coolies mixed freely with the rest of the population without communicating the disease. An obvious suggestion on the facts as reported is that some one should be held responsible for this useless destruction of human life, the causes of which are purely local and remediable. Fire and sulphur were used as disinfectants, but if it may be suggested that the real cause was not in the air but in the bustees, it would appear to follow that, in default of other remedy, the most effectual would be burning the bustees and providing better accommodation for the work people.

24. In *Howrah* town, which had a cholera mortality of 7·78 per 1,000, bad water was an assigned cause.

25. The *Suburbs of Calcutta* yielded a death-rate from cholera of no less than 9·62 per 1,000, and in regard to certain areas of them the following notes are introduced:—

"*Manicktolla* is the most filthy part of the suburbs, the land behind the houses being used as "public latrines. In fact, all the bustees in this area are in an extremely insanitary condition" from the filth and refuse lying about, and the "ponds, hollows, and low lands being the receptacles of "liquid sewage and filth."

Garden Reach and its bustees are in a similar condition, as are also about a dozen other areas. In some cases the state of things scarcely admits of description, and yet the suburbs are in reality part of the capital of India, and some sanitary work has been professedly done for the suburbs during the past 20 years. The only effectual remedy for so deplorable a state of matters is to include the suburbs within the municipal boundary of Calcutta, and to provide an efficient and active sanitary administration for the entire area.

26. *Nuddea* had a cholera death-rate of 5·79 per 1,000, rising in Gangni town to 17·27 per 1,000. "On the whole its severity, this year, is attributed to bad water-supply, which was general throughout the district owing to scanty rainfall causing the tanks and water reservoirs to run very low, to defective drainage, to the filthiness of the villages, and to want of wholesome food." The excessive death-rate of Gangni is attributed to the water having been taken "from the pools in the khals, into which only local drainage enters, and in which bathing both of men and animals is carried on." Other examples of most deplorable sanitary neglects and their results are cited from the Nuddea report.

27. In one of the old cholera centres, Jessore, there was a 4 per 1,000 cholera death-rate. This place has suffered from cholera since 1817, but the lesson supplied annually by the epidemic appears to have produced little result, for the town still has the following death causes to contend with:—"Its unhealthiness is in some measure due to the insanitary conditions obtaining in it, for the general conservancy is not properly attended to; the privies are filthy, the attendance of the mehters being irregular, the night-soil is not properly trenched, the drainage is defective, as most of the drains are mere open ditches, and some of the bazaar drains are obstructed by refuse from the shops, the culverts being used as receptacles for rubbish. Very nearly all the tanks contain organic matter, being open to every description of pollution, and the graves are not dug sufficiently deep."

28. The case of *Dacca* town is again referred to in the present Report in connexion with its improved water supply, which was supposed, on the cholera water theory, to afford protection against the disease. Nobody doubts the benefit of good water to the health of a community, but a fundamental position in sanitary work is, that no amount of the purest water by itself will protect a people from diseases due to causes not connected with water. In Dacca town the cholera death-rate in 1883 was ·59 per 1,000. But in 1884, in spite of the good water, the rate rose to 2·88 per 1,000, due to the following assigned causes:—"The drainage is very defective. There is an absence of all natural drainage. The levels of the streets and lanes are very irregular, and the courtyards of houses are, as a rule, a foot or more below the level of the roads and lanes, precluding house drainage connexion with the main drains. The night-soil and scavenging establishments are below the requirements of so large, so dirty, and so irregularly built a town as Dacca. It has not yet been provided with a sufficient number of public latrines, and worse than all many gors, well privies, and contaminated wells yet exist." All these defects are well known local causes of cholera, apart from the state of the water-supply, and they will continue to levy their death tribute year after year until suitable remedies are applied. No doubt much bad foul well water is still used, and this appears to be one of the present results of the new municipal *régime*, for the Sanitary Commissioner tells us that, "it is found hard to get the native members of the municipality to believe that well-water in Dacca is only diluted sewage." It is clear that what Dacca requires is thorough sanitary improvement, the filling up of bad wells and foul cesspits, cleanliness, and good drainage. It is also clear that, with the present relative levels of houses, house compounds, and streets, no house drainage is possible, and that the only alternative is collecting all sewage and removing it by hand labour.

29. The case of Dacca has been here referred to on account of the contradiction it gives to the one cause theory of cholera, and we may here contrast with it the statement of the subdivisional officer concerning a severe outbreak in some villages in the Dinapore subdivision. He says, "The most remarkable point in regard to the outbreak is that the disease broke out in places where cleanliness was very rigidly observed, while on the other hand villages, which were, so far as outward appearance went, in a filthy state, escaped the epidemic altogether."

It follows from this Report that, as is well known, the mere surface conditions of a town or village are no test of its liability to cholera. But it also shows that something other than local conditions must be present before cholera can break out, and this is the epidemic itself. The surface clean villages which were attacked had their own localizing conditions, but generally these are under the surface, and are to be sought in foul compounds, dungheaps, cesspools, and foul wells as the result of foul subsoils. Why the apparently filthy surfaced villages escaped we know not, but it is highly probable that their turn will come in due time.

30. *Faridpur* town had a cholera death-rate of 6·13 per 1,000, and the following facts about the disease are stated by the Civil Surgeon:—"Those cases which occurred in the town were in the persons of those who had nothing to do with any previous case of cholera." None of the attendants on the sick, averaging eight per case, suffered from cholera. Cases presented themselves among persons using all kinds of water. The disease was most severe in low damp places hedged in by trees, and ill ventilated and dirty. Neighbouring villages obtained their supplies from the cholera-stricken town bazaar without being attacked by cholera. "The jail situated in Ward No. 3, having an average population of nearly 200 persons, remained altogether free from the disease, though cases occurred within a few hundred yards from the garden, and prisoners were admitted into the jail from infected thanas of the district."

These facts belong to a class showing apparently the simple non-transmissibility of cholera from person to person.

31. *Port of Calcutta.*—Cholera among the river population was more severe in 1884 than during the previous year. The average population of European seamen was 1,684, among whom there were 67 cholera cases and 36 deaths, equal to 21·37 per 1,000. The native floating population, averaging 25,409, yielded 138 cholera deaths, or 5·43 per 1,000. No account is given in the present Report of the local causes.

32. It will have been observed that nothing new in the history of cholera has been revealed by the experience of 1884. It is the old history repeated year after year of great numbers of population

groups scattered over the surface of Bengal living under very bad sanitary conditions and a cholera epidemic, whence coming no one knows, but swooping down in a most irregular manner on certain of these groups, and leaving others of them until a future season, and the practical conclusion is simply that had these attacked groups been in a healthy condition they would almost, if not altogether, have escaped the epidemic of 1884.

33. *Small-pox.*—The registered mortality from small-pox for five years preceding 1883 was ·29 per 1,000; the rate for 1883 was ·14 per 1,000; and that for 1884 was ·28 per 1,000. In 1883 there were 9,714 small-pox deaths, and in 1884 the number registered was 18,533, or double the preceding year's mortality. The disease existed in all the 45 registration districts, with two exceptions, Darjiling and Jalpaiguri, and in 424 registration circles out of 649; but the mortality was returned from no more than 6,749 villages out of 227,615. Hence it follows that small-pox covered nearly the whole area of Bengal, but the death-rates were purely local. The attacks were endemic, but the area was epidemic. This is the usual history of Indian epidemic diseases. Severe as was the outbreak of 1884 in Bengal, it was a comparatively small matter when compared with the great small-pox epidemic of the North-West Provinces and Oudh for the same year, during which upwards of 200,000 people perished.

34. In Bengal every month of 1884 yielded small-pox deaths, and, as will be seen from the following abstract, there appears to have been an entire epidemic in the course of the year.

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January	826	July	1,312
February	1,411	August	717
March	2,637	September	336
April	3,715	October	354
May	3,705	November	392
June	2,543	December	585

Out of 96 towns 34 registered 2,711 deaths, or a death-rate of 1·10 per 1,000 on the total town population, while in the rural districts there were 15,822 deaths, or ·24 per 1,000. As bearing on the present state of vaccination, it is important to point out that of the total year's mortality from small-pox, which amounted to 18,533 deaths, there were 4,193 deaths at ages under one year, and 13,395 under 12 years of age. The highest rates were returned from four districts in the Patna division. The highest small-pox rates in the towns were 6·91 per 1,000 in Gya, 8·23 in Hazaribagh, and 9·05 per 1,000 in Bhagulpore. Dinagepore town had only one small-pox death among 12,560 people, an exemption which the magistrate accounts for by stating "that as the Dinagepore town is "yearly almost wholly burnt down and thoroughly cleansed by fire, he thinks that for this reason "perhaps small-pox gets no hold on the place." It would appear as if there was truth in this view, inasmuch as the death-rate from all causes in 1884 was only 13·61 per 1,000, and its previous five years' average 22·83.

35. *Vaccination.*—There is full information of a departmental kind on the vaccination work for the official year 1884–85, but we shall confine our remarks to the working results.

The establishment was as follows:—

Superintendents		8
Deputy Superintendents		12
Inspectors and Native Superintendents		85
Head Vaccinators		23
Vaccinators, circles	276	
" municipal dispensaries	213	
		489
Apprentices		56
Licensed Vaccinators, circles	1,067	
" " municipal	27	
		1,094
Total staff		1,767

Leaving aside unsuccessful operations, those returned as successful were,—

Primary vaccinations	1,457,105
Secondary vaccinations	5,489

These numbers represent 99·38 per cent. for the primary, and 48·22 per cent. for the secondary, operations. The Vaccine Department does not apparently cover the entire population of the province, which is 66,163,884, for the returns apply to a population of 50,571,655.

36. In estimating the value of the protection afforded we ought, however, to adopt the larger rather than the smaller population. But we have no means of comparing the vaccination operations with the births, for the rate of 23·51 per 1,000 for 47 towns is evidently below the truth. We may, however, safely estimate the annual birth-rate at 30 per 1,000, and on the total population of the province there would on this estimate be 1,984,916 births, while for the smaller population within the

vaccination area the births would be 1,517,150 approximately. Either number would roughly represent the available subjects for infantile vaccination within their respective areas. But, as we have seen, the primary successful operations in 1884–85 were 1,452,105, and when these are arranged according to age, they give 211,386 vaccinations under one year, and 977,894 between one year and six years, so that only about a seventh part of the births is represented by the operations under one year of age. The practical result hence appears to be that although the total vaccinations do not fall very much short of the births within the vaccinated area, they are so distributed among the ages as to afford little protection to the infant population. This defect points to the necessity of an improved direction of the work towards the ages under one year.

37. *Fevers.*—The most unsatisfactory portion of the year's sanitary history in Bengal is the great loss of life from "fevers," which, as the statistics show, cut off 966,233 people in 1884. As yet we know very little of the nature of these fevers, and as on a correct knowledge of them depends much of the possibility of dealing with their causes, it seems not out of place for us strongly to advise that there should be inquiry and report on the subject. But whatever errors in diagnosis there may be in the returns, these have prevailed in other years, and the loss of life from this class of diseases in 1884 is the greatest on record, while it shows a great loss of working power among survivors. The deaths since 1871 have been as follows :—

Years.	Fever Deaths	Deaths per 1,000.	Years.	Fever Deaths.	Deaths per 1,000.
1871	169,505	2·56	1878	743,887	11·23
1872	237,868	3·59	1879	632,260	9·41
1873	308,645	4·59	1880	689,605	10·43
1874	323,721	4·27	1881	946,911	14·23
1875	368,087	5·56	1882	929,943	14·06
1876	561,582	8·49	1883	915,766	13·81
1877	711,086	10·75	1884	966,233	14·60

The only satisfactory part of this abstract is that it shows improved registration of deaths; but if the local fever causes had not increased the liability to fever attacks among the population, there is no apparent reason why the fever death-rate of the scarcity years, 1877–78, should not have undergone continuous reduction when the emergency has passed away, instead of shewing the large augmentation of subsequent years.

38. Fever mortality covered the whole province in 1884, for deaths from it were returned from every one of the 649 registration circles, and out of 227,615 villages 147,466 returned deaths. It is probable that few, if any, of the villages escaped attacks.

Deaths among males averaged 15·94 per 1,000 of the total population, and the deaths among females were in the ratio 13·28 per 1,000. The provincial death-rate was 14·60 per 1,000, and the preceding five years' mean was 12·38 per 1,000. The highest rate of the year, 30·40, was returned from Rajshahye, where 40,698 people died of fever. Nudden, the chief fever district, lost 48,383 of its inhabitants, or a death-rate of 29·22 per 1,000. The previous five years' rate of this district, which includes a great fever epidemic, was 31·72 per 1,000, showing a reduction of 2½ per 1,000, but the high rate in Rajshahye shows a real epidemic increase of 6·37 per 1,000. Not one of the 26 towns escaped. The deaths among them numbered 31,701, or 12·89 per 1,000. In a number of them the rates were as high as between 2 and 3 per cent.

39. The following abstract gives the monthly deaths in 1884 contrasted with the monthly rainfall for the same year, and the mean monthly mortality for the previous 12 years, 1879 to 1883 :—

Months.	Fever Deaths, 1884.	Rain 1884. In.	Fever Deaths, 1879–88.
January	35,385	·05	73,828
February	69,933	·79	57,918
March	78,762	·36	58,362
April	76,711	2·63	59,548
May	71,070	6·06	55,053
June	68,523	12·04	49,359
July	65,958	11·27	55,662
August	77,188	9·38	62,756
September	75,375	8·97	66,555
October	88,424	5·08	80,794
November	113,836	·58	99,899
December	104,582	·04	100,123

This table shows that the months of highest fever mortality in Bengal are October, November, December, and January, during which there fell only 5·7 inches of rain in 1884. The fever in these months was not the result of absolute quantity of rain. There was cessation of rain, drying up with its disengagement of malaria, together with low and variable temperatures. These atmospheric conditions may be assumed generally as those usually present during the months of maximum fever mortality. But the high cumulative rainfall of the preceding months must also be borne in mind, and the effect of this on the subsoil before the drying up began must be considered.

40. The following facts connected with local fever prevalence are of importance. The former great fever area of Burdwan had a fever death-rate of 18·81 per 1,000, against a previous 12 years' rate of 23·77 per 1,000. There has been drainage work carried out in this district, but, besides this, the rainfall in 1884 was under the average.

41. In the parts of Bankura which suffered most from fever there is marshy undrained land covered with jungle. But the laterite tracts, "where the soil is porous, and the natural drainage "very good, enjoyed comparative immunity from the disease, and here it is uncommon to find cases "of advanced malarial cachexia."

42. There is an account of fever and its local relations in *Midnapore* by Dr. Ghose, Officiating Sanitary Commissioner, of so much interest and importance to the whole question of fever etiology that we shall quote it. Referring to 13 villages, he says:—"All these villages, with the exception "of Churs Najooreh and Bilkota, are within the protective embankment along the right bank of the "Roopnaryan river. The drainage from them is perfect, *i.e.*, all tide and flood water is excluded "by means of embankment and sluice gates, and surface channels drain out the last dregs of rain-"water through these sluices when no longer required for paddy cultivation. The result is that no "vestige of malarious cachexy is to be seen in the people. But the people of Churs Najooreh and "Bilkota, living on churs generally inundated during the rains, have well marked signs of malarious "disease in them. Those who wish to study the effect of drainage on malarial fevers and on "agriculture ought to come here and see the condition of the people within the embankment. In "the two villages on the churs outside the embankment the paddy crop is uncertain, liable to the "rotting effect of inundation and the parching effect of drought. The pulses, as a rule, are affected "by worms, the oil-seeds grow but indifferently. The only paying crop is water melons, which do "well in dry weather on all *chur land*, whereas within the embankment, where no such thing as a "bhil could be seen, the paddy was perfect, and I saw in many places, after the paddy had been "cut down, the pulses and oilseeds had been sown broad cast and doing very well. Those who "declare that well drained land is unfit for paddy cultivation ought to visit these places. What "struck me most in all these villages was the entire absence of low jungle, a state of things I have "not seen in the deltaic portions of Bengal. I also observed that the people do not dig ditches in "village sites for taking earth for their plinths or walls, but uniformly take nine inches from the "surface of their fields, which is soon replaced by silt washed down by rain." Their water sources are bad, but the tanks are kept clean. Dr. Ghose further says that in certain thanas, Keshpur and Midnapur, the villages are below the high-level irrigation canal level, and malarious. Carefully observed facts of this kind are precisely what we want to enable us to understand the causes of these fevers. Here we have a distinct case in which properly arranged surface drainage is detrimental to the growth of jungle, and is favourable to the growth of paddy crops, usually supposed to require flooded ground, with its consequent subsoil stagnation, and where the people are saved from the ravages of fever, the whole being done by simply opening and closing flood sluices at the proper time.

43. We shall now take a case of a very different kind, which shows the great danger of adopting the fallacy that a sanitary work of drainage once accomplished may be left to itself.

Some years ago the water of the Damoodar was brought into the channels of the Kana Nuddi and Sarasiti to produce a flow, to improve the drainage, and to bring water to the villages. The work was accomplished at a large outlay, and now the Subdivisional Officer of Serampore tells us that the work "is now going to ruin for want of little attention and a trifling amount of expense." When first done it was attended by immediate improvement in the health of the people, and in 1884 the people along the partially silted up channels are said to have "suffered very much," and he says, "I must express my total inability to understand a policy which spends lacs of rupees on important "sanitary work, and then leaves that work to go to ruin in a few years in order to save an annual "expenditure of a few hundred rupees."

The real reason appears to be that the authority which took charge of the work had no adequate knowledge of its sanitary relations, otherwise we must adopt the conclusion that "the few hundred rupees" a year were considered to be a fatal objection to keeping the channels open. Any way the case needs being looked into and the people's health protected.

44. In the 24-Pergunnahs there was less fever generally than in 1883, but nevertheless some villages suffered from excessive fever-rates. In several villages in Bussirhat thana many of the children were found to be pale, scrofulous, and suffering from spleen. "The sanitary condition of "these villages is very unsatisfactory, the drainage bad, and the water-supply worse." Much of the malarial disease in these places is due to obstruction of outlet drains and general stagnation of subsoil water. The observation is made anew by the Deputy Sanitary Commissioner, that where there is much water there is less fever, and that a feverish locality is a moist rather than an absolutely wet one.

45. A case is mentioned where closing a river channel by vegetation and other matters had spread fever over the neighbouring villages, in consequence of which Dr. Ghose advised that surveys should be made for remedying this fever cause. The reply of the magistrate was that "it is useless to ask "engineers for plans of works which will never be carried out, and would be of doubtful utility if "carried out." On this decision the Sanitary Commissioner very properly remarks "that the "question as to the manner in which drainage is to be effected in places where the old drainage "channels no longer exercise their original functions is a most important sanitary one, and should "be considered in the Public Works Department as funds and opportunity permit." Of course it

should. Work of this class is a part of the ordinary sanitary survey work which ought to be part of any administrative arrangements dealing with these delta lands. The results of neglect of these conditions are stated by the Sanitary Commissioner that, on visiting the village schools, he found the health of the children very bad. "There was evidence of the effects of malarious poisoning in "nearly everybody I saw." There were many deserted homesteads, and the population had diminished.

46. Nuddea district was the seat of a severe fever epidemic a few years ago. Improvements were projected, but we know not to what extent they were carried out. Any way, the fever mortality, which on a five years' average had been 31·72 per 1,000, was 29·22 per 1,000 in the year under review.

47. It would occupy too much space to abstract all the information which this Report contains on the local etiology of fever. The details we have given will show its general nature, and it will be observed that great stress is laid on obstructed drainage as a fever cause. Suppose a new country similar to the Gangetic delta with all its watercourses and affluents free, so that drainage was sufficient and without obstruction. Such a country would in all probability be free of fever when first settled. But this most recent Bengal experience teached us that if from any neglect on the part of the inhabitants the drainage channels became obstructed so as to back water the subsoil there will be fever.

Real preventive sanitary work having been neglected, deterioration of sanitary condition and the advent of fever and other epidemics is simply a matter of course, and no future sanitary proceedings can ever restore a locality where epidemics have once shown themselves to its original condition. All that subsequent sanitary engineering can do is to remove drainage obstructions and keep them away for the future, and this can only be done by examination, by present work, and by future engineering supervision. The work is strictly a sanitary one, and must be so regarded if any good is to be done; this appears to be the teaching of the present Report, and it may be taken safely as ground of action. There is less said than in former Reports on the state of the villages; this remains, no doubt, much the same as it was. If the villages are improved as they ought to be the fatality of fever will become less year after year, but the amount of fever is connected with the subsoil water, which in its turn is dependent on the drainage outlets, and it will continue pretty much as it is until they too are made efficient.

48. *Fever in the Port of Calcutta.*—Among European seamen in port there were 297 admissions from "simple fever," 158 from malarious fever, of which two proved fatal, and there were seven cases and five deaths from enteric fever. There were only four fever deaths in 1883. The port floating population yielded five deaths from malarious fever, and ten from simple fever. There was nothing worthy of remark in the facts, except the much lower mortality than prevailed among the country population.

49. *Bowel Complaints.*—Under this head were registered 58,376 deaths, or ·88 per 1,000 of the population, against ·82 per 1,000 in 1883, and ·81 for the preceding five years' mean. Deaths from this cause were returned in 1884 from 627 registration circles out of 649, and from 24,150 villages out of 227,615.

The seasonal mortality was as follows:—

Months.	Bowel Complaint Deaths.	Months.	Bowel Complaint Deaths.
January	4,865	July	4,525
February	3,932	August	5,089
March	4,634	September	4,590
April	5,000	October	4,348
May	5,050	November	5,706
June	4,842	December	5,788

The death-rate was ·79 per 1,000 for the districts, and 3·24 for the towns, or fourfold. The Sanitary Commissioner calls attention to the fact that "the mortality in hot, rainy, and cold months "follows no rule, indicating very defective registration."

Among European seamen in port there were 125 cases of diarrhœa and 80 of dysentery. Three of the former and two of the latter proved fatal.

50. *Deaths from injury* numbered 24,674, of which 2,612 were from suicides, 1,591 from wounds, 10,078 from accidents, and 10,393 from snake-bites and wild beasts.

51. *All other causes* accounted for 176,373 deaths. In concluding this abstract of the disease history of 1884, it may be noted that European seamen yielded 15 cases and three deaths from sunstroke and heat apoplexy. Among the greatly more numerous floating Native population there was only one case not fatal. It is worthy of remark also that there were 24 seamen treated for scurvy, of which disease one died, and that 17 cases were in six New York vessels; there was lime-juice on board, but the officers did not appear to know the quantity which should have been issued.

52. *Sanitary works, Civil.*—The income of 175 municipalities in Bengal for the year 1884 was Rs. 32,78,326, of which 38 per cent. was appropriated for sanitary purposes. This money was laid out on the following objects:—

	Rs.
Conservancy and latrines	3,99,293
Conservancy establishment	2,82,206
Drainage	1,05,973
Water-supply	1,35,181
Disposal of dead	8,341
Markets and slaughter-houses	24,042
Vaccination	12,481
Treatment of sick	1,87,185
Other sanitary works	78,087
Total sanitary	12,32,789
Roads, &c.	6,28,578
Total outlay	18,61,367

Deducting Rs. 1,99,666 spent on vaccination and treatment of sick, the amount spent on sanitary works and measures properly so called would thus have been Rs. 10,33,123, or in round numbers 103,000*l.* Compared with the preceding year's outlay there was an increase of Rs. 91,342 on conservancy and latrines, but there was a decrease of Rs. 43,654 in the establishment charges, so that probably the service was less efficient notwithstanding the larger outlay.

53. Details of local sanitary measures are given in the Appendix, and include a large number of items under different heads of expenditure already stated. No doubt good work, though on a small scale proportionately to the requirements, had been done in the course of the year; many wells were sunk anew or improved, tanks were put in better condition, and many were excavated. Local advances in drainage were also made, and the following statement about drainage improvements in Nuddea is of importance:—"Further improvements to the drainage of the fever-stricken district of "Nuddea were effected, the work consisting of the construction of a good many arched culverts and "wrought-iron girder bridges on masonry abutments, of the completion of the works on the road "from Chagda railway station to Bougong, and of the construction of four arched culverts on the "Chapra and Nishhindpur road. These culverts span drainage channels." Many drainage schemes have been prepared, and some have been sanctioned, but are delayed from want of funds. These works, which are intended to restore water-ways, will no doubt be of benefit to the health of districts when they are carried out.

54. There is one point in the drainage of Murshidabad which requires notice. "Owing to want "of proper flushing the two main channels within the Shamnagar and Mohimapur wards did not "work well through the pipes, which are only six inches in diameter. The pipes are already a good "deal choked up with silt, and there are no means of cleansing them unless they be taken up and "relaid, a work requiring much attention and enormous cost." This result involves a defective application of the following principles of Indian sanitary engineering work:—

(1.) Rainfall should always be conveyed to an outfall by open shallow impervious surface channels. Unless under special conditions built sewers or pipes are not necessary for such purposes.
(2.) Pipe-sewers should be only applicable to house drainage purposes.
(3.) No pipe-sewers should be used unless there is sufficiency of house water available to keep them clean, or of water for sewer flushing.
(4.) When house drains cannot be had in combination with sufficient water it is better to trust to hand removal of house sewage.
(5.) Where surface drains are used for removing foul water it is necessary to provide sufficient water to flush and keep them free of offensive deposit.
(6.) It is by no means an adequate solution of the drainage question to execute drainage works and then to leave them to themselves. Sanitary works require careful oversight after they have been completed. As regards the obstructed sewers, the usual way of dealing with such cases is to pass rods along the pipes to loosen the deposit, and to wash it out with water. But, with proper care, the silt might have been kept out of the drain pipes.

55. In Patna municipality, in defect of funds for a larger scheme, provision has been made for keeping the rainfall from stagnating by a system of pucca surface drains. "The works have, it is said, already proved of the greatest service."

56. A somewhat similar work was projected at *Chittagong*, where drainage is very much required. "Surveys, reports, estimates, &c. were submitted by the Public Works Department, but, as usual "with these things, the labour expended in making the plans, &c. has all been wasted in some "pigeon-hole at head-quarters."

57. Plans and estimates had been prepared for draining the Rajmehal swamp, but the local proprietors would not contribute to the cost, which the Deputy Commissioner regrets, because of

"the extreme unhealthiness which has led to the almost depopulation of the tract once teeming "with a wealthy Mussulman population." This swamp is on part of an old bed of the Ganges It is much to be regretted that this work is stayed by the people whose interests it would benefit.

58. As we have already seen, about 10,500*l.* were expended in the course of 1884 by municipalities on drainage. The amount is so small, in comparison with the necessities, that we may recur to a proposal we have often made to try to obtain relief from the dangerous effects of rain stagnation by filling up excavations, improving the surface, and cutting surface channels to allow the water to escape. This could all be done by the people, or any way at a very small outlay.

59. *Water-supply.*—The most important item under this head has been the completion of Burdwan waterworks, which were opened by His Honour the Lieutenant-Governor on the 4th November 1884. "The measure has proved, it is said, to be of great benefit to the inhabitants of the northern "portion of the town, in which pipes have been laid and hydrants set up." At first many of the inhabitants were unwilling to use the filtered water, but now about 99 per cent. of them do so, and opposition has died away. There are 60 hydrants, but more have been applied for, and the supply of water is ample. House connexions have also been sanctioned. In this, as in other similar cases, we must repeat a caution we have often given, and this is, that whether the new water-supply, especially after completing the house connexions, is to be a benefit or an injury to health depends on the drainage provisions made for keeping the water after use out of the subsoil. Water-supply and drainage are not two separate works. They are one combined work.

60. The waterworks of Dacca have been further improved, and we are glad to see that "the "munificent Nawab Assanoolah has, in commemoration of the visit to India of their Royal Highnesses "the Duke and Duchess of Connaught, extended the waterworks northward up to Nawabpore "Road." This is stated to be of great benefit to a poor and crowded neighbourhood. India at present affords abundance of opportunities for men of wealth and influence to bestow similar benefits on their poorer fellow-subjects. The example is one which should be commended and followed.

61. "In the Bhagulpore town a scheme of water-supply has been sanctioned by Government, and "material and plant are being collected for carrying it out." We are glad to learn that in this instance Government has placed the aid of the Superintending Engineer and his subordinates at the service of the town free of cost.

62. Improvement of the water-supply in Nuddea district is under inquiry, one object of which is to ascertain, if possible, to what extent the great prevalence of epidemic diseases there is due to bad water. A curious fact is stated about well water, and this is that the people rarely use it because it gives them nasal catarrh.

63. The Commissioners of Howrah were arranging for a water-supply, in the benefits and costs of which they proposed that other riparian municipalities should join. An assembly of delegates of these municipalities was summoned, and it appeared probable that they would join in the work. In this case the services of the Executive Engineer were lent by Government.

64. These instances have been selected to show the chief objects on which money has been spent, but they belong to municipalities. There is no special report on village work, which so far as concerns epidemics is the most important, unless the improvements reported in *districts* can be accepted as such, but even with this qualification, it is quite safe to say that the work in districts is general in its character, while true village sanitary work is strictly local. There is one suggestion made by the Magistrate of Shahabad on this subject in which we entirely agree. He says, "I think "that the attention of Government might be drawn to the propriety of taking special sanitary action "in its own villages, and of assigning a per-centage on the rents for the purpose." If this course were followed health and life would be saved, and an example set forth that the Government meant what it advocated to be carried into action.

65. An important step in sanitary legislation was taken by the passing of the New Bengal Municipal Act of 1884, which appears to confer ample powers on the local authorities. The amended Poori Lodging-house Act was also passed. Another important Act, "The Bengal Local Government "Act," by which district wards will be appointed for sanitation outside municipalities, was passed in April 1883, and awaited sanction by the Supreme Government. So far as we can judge from the brief particulars of its provisions it might enable the District Boards to undertake village work; but there is rather more said about inspecting than is said about execution, for the one is of very little use without the other.

66. There is one matter connected with railway administration which the Sanitary Commissioner very properly says "requires the serious consideration of the Government," and this is the deplorable condition of the water-supply at many stations, a defect easily remedied, and if this water has any relation to liability to cholera among Native passengers, it surely ought to be at once superseded by a wholesome supply.

67. Another urgent matter dwelt on by the Sanitary Commissioner is the present state of law and practice for disposal of the dead. It appears to be a general practice, chiefly among Mahomedans, to bury dead within the precincts of villages, or even within houses. It is obvious that procedure of this kind in an epidemic country ought not to be allowed. Among other Native communities dead bodies are simply thrown into rivers, to the danger of the public health. Remedies for both practices might surely be discovered and applied.

68. *Personal proceedings.*—Under this heading and its appendices is given a detail of inspecting work done by the Sanitary Commissioner and his staff, which includes a large amount of useful information on the present condition of the places visited. Dr. Lidderdale himself inspected 27 municipal towns. The seven Deputy Sanitary Commissioners inspected 2,712 villages in 1884, and the eight Deputy Superintendents of Vaccination inspected 2,574 villages. It is satisfactory to be told that no more than 205 villages showed signs of retrogression. A large number of villages was inspected by subordinate officers, but the results are not considered of sufficient importance to be quoted.

69. We have already given an extract from a report by Dr. Ghose, who appears to have devoted much attention to this inspecting work, for he not only describes the defects which came under his notice, but, so far as we can judge, he has traced them to their causes. For example, he tells us that an area of country within which the stations of Dum Dum and Barrackpore are situated was at one time inhabited by a flourishing population, but within the last 30 years or so this tract of country has become very malarious, a result which he considers to have been caused by derangement of the whole water and drainage system by partial silting up, and the discharging channels have been interfered with by a series of embanked roads and railroads, so that the free passage of water to the salt-water lakes has been impeded. "The whole area has thus been converted into blocks of "marshes, the culverts and bridges acting only when the country is overflowed." If this view were confirmed by special engineering inspection, it would go to show that the present drainage outlets allow only the wholesome part of the inundation water to escape, while the malaria producing portion is retained.

Dr. Ghose moreover tells us that "no village can be said to have a supply of pure drinking water." This statement condemns the sanitary condition of the soils, subsoils, and surroundings of the villages, because on these depends the sanitary state of the water-supply, and he sums up the results of his inspections in the following words:—"From my observations I am of opinion that want of drainage "and bad water-supply are the general and crying evils of all these districts. The former has made "malarial fevers and the latter cholera the endemic diseases of the country;" the bad water being, as we have said, an index to generally polluted site.

70. There is a large amount of detail in the other reports of a similar kind, giving with more fulness the sanitary state of the villages. There is a sad uniformity in all of them. But the one consolatory fact is that, excepting the cases in which disease is due to the condition of the tracts of country within which these villages are situated, there are no local disease causes in the villages which could not be removed by the people themselves and without costly sanitary works. If cholera, small-pox, and fevers only affected a village by itself and left the country free, there might be some possible argument for non-interference, but the epidemic history shows that the great losses of life which tend to impoverish the country directly or indirectly are simply the results of the aggregate influences of single village outbreaks. The causes are local and the results general. This is the law revealed by statistics, and these sanitary inspections, which have been ably conducted by the Sanitary Commissioner and his subordinates, have led us directly to the causes with which Government and its executive officers have to deal. This is the final result of the Report for 1884.

71. Before concluding, we may refer briefly to a report on the suburbs of Calcutta by two of the Native Deputy Superintendents of Vaccination. In this report they have clearly localized disease causes which have made the large population inhabiting the suburbs proverbial for their liability to epidemics. There is, however, nothing in the report which has not been discussed by us in former years, but what it does do is to strengthen the evidence for the necessity of extending the Calcutta Municipal Acts over the entire area, for the work is of such a nature as to preclude its being done bit by bit by the local agencies.

Lastly. The sanitary defects exposed in the Report, and the great losses of life consequent on their existence, have, we fear, consigned the good work actually done to a subordinate position in this review. And we desire, in conclusion, to express our satisfaction with this work within the very limited area which it has as yet covered.

The facts we have given show how deeply the public health and economic interests of the vast population of Bengal are involved in prosecuting these improvements over the whole country, and they clearly show the need of a more efficient sanitary executive, such as was provided for in the way of recommendation by the Royal Commission on the sanitary state of the Indian Army nearly a quarter of a century ago.

25th May 1886.

No. 5.

Memorandum of the Army Sanitary Commission on the Report of the Sanitary Commissioner for the Punjab for 1884.

1. The population element used in this Report is that of the census of 1881, namely, 18,842,264. The registered births in 1884 were 809,912, which yielded on the census population the high birth-rate of 42·98 per 1,000; this, however, is only a mean of 32 registration districts in which the lowest registered rate was 18·91 per 1,000 in Peshawur district, and the highest 53·53 per 1,000 in

Sialkot. But the really lowest birth-rate was 12·04 per 1,000 in Simla, marking apparently the uncertain nature of the population element there, while in the other districts no allowance can be made as yet for increase of population since 1881, because the rate of increase in the districts is not known; consequently the birth-rates are generally too high.

2. The deaths registered in 1884 were 660,298, yielding a death-rate on the population of 1881 of 35 per 1,000, which is likewise a mean of 32 district rates, the lowest being 14 per 1,000 in Peshawur, and the highest 66 per 1,000 in Ludhiana.

The proportional ratios between the sexes were 114·77 male births for 100 females, and 109·12 male deaths for 100 females.

3. The death causes in 1884 were as follows:—

Diseases.	Deaths.	Deaths per 1,000.
Cholera	614	0·03
Small-pox	16,416	0·87
Fevers	465,556	24·74
Bowel complaints	16,346	0·97
Injuries	5,512	0·29
Other causes	153,854	8·16
All causes	660,298	35·03

4. As will be seen, cholera was by much the least fatal death cause in the Punjab in 1884. For every death from cholera there were about 27 deaths from small-pox, and 758 from fever. This subject of comparative mortality is of great importance in epidemiology, and we shall here give the deaths from each disease for a series of years, taking for granted that the registration errors have not varied materially.

Years.	Registered Deaths.		
	Cholera.	Small-pox.	Fevers.
1868	532	23,759	151,337
1869	9,258	58,195	272,956
1870	469	27,163	275,093
1871	266	25,834	213,548
1872	8,727	23,738	264,711
1873	148	25,699	219,909
1874	79	12,026	190,613
1875	6,246	13,611	279,825
1876	5,738	10,254	351,286
1877	22	12,296	219,281
1878	213	40,271	440,492
1879	26,125	32,489	472,939
1880	274	9,145	327,727
1881	5,207	6,749	355,279
1882	39	6,379	346,680
1883	190	12,103	306,164
1884	614	16,416	465,556
Total	64,152	378,127	5,153,396

5. The following results of this table are of importance, for we learn from it that of the total deaths from these three epidemic diseases, no more than 1·13 per cent. were due to cholera, 6·67 per cent. were due to small-pox, and above 92 per cent. to diseases classed as "fevers."

6. It will also be observed that the two first epidemic diseases, cholera and small-pox, are very irregular in their incidence and in the mortality they occasion from year to year, while the proportions of deaths assigned to fever, although also variable, are not so much so as the death-rates from the other two diseases. All three are subject to rapid augmentation and decline in particular years and groups of years.

7. We have not the data for 1867, which was one of the great Hurdwar fair years, for the three diseases, but in that year 43,146 people died of cholera. This great epidemic was assigned to the fair and its results, but many years ago we showed by the statistics that the disease underwent increase all over the north of India at the time. The preceding table allows us to introduce a correction for the next great Hurdwar fair of 1879, for it shows that although there was a great augmentation of cholera mortality in that year, it was accompanied by a still greater increase of the small-pox and fever mortality, insomuch that the deaths from fever were the highest in any year of the series; the small-pox deaths were also the most numerous, with one solitary exception, and cholera deaths were also the most numerous. The average annual mortality during the 17 years in the table from the three diseases amounted to 328,863, while the deaths from the same diseases in the Hurdwar fair year, 1879, were 548,553. The increase of cholera deaths was a very small matter indeed, when compared with the total epidemic increase of the fair year. It seems not unlikely that there are years of periodic increase of epidemics all over the country; anyway we should scarcely be justified in assuming the Hurdwar fair as a *vera causa* of the enormous increase of small-pox and fever mortality during the year when it was held.

8. The cholera mortality of 1884 amounted, as has been shown, to 614 deaths, of which 577 took place in country districts, and the remaining 37 in towns. One of the most singular facts about this cholera was its distribution. There were single deaths at long distances from each other, as if to show that the disease covered the whole country, while the disease was active only over limited areas. Thus out of 32 districts, 21 escaped entirely. Six districts yielded each one death. One district returned 2 deaths, one returned 7, one 12, another 24, facts which show the distribution, but not the intensity, which was reserved for Kangra district, where out of a population of 727,006 there were 526 cholera deaths. A similar distribution took place in the towns, 8 of which out of 49 yielded all the deaths, 37 in number. But of these, 17 deaths were yielded by Delhi and its suburbs, and 13 by Jullunder and its suburbs. All the cholera deaths of the year were returned from 26 registration circles out of 444 in the province, and from 97 villages out of a total of 35,972.

9. Tried by any of the usual standards, no account can be given of the facts. Here we have a case in which the same defective conditions as to water, drainage, deficient cleansing, intercourse between affected and unaffected localities, infective influence, if such there be, existed as usual, and the statistics show that cholera was over the country, and yet it swoops down on one district only, and we shall now see whether in this district there was an added condition which may fairly be assumed as a cause of these purely local facts. And first, as regards the seasonal incidence of cholera, which was as follows:—

Months.	Cholera Deaths.	Months.	Cholera Deaths.
January	1	July	39
February	—	August	141
March	2	September	29
April	—	October	—
May	218	November	4
June	178	December	2

This table bears marks of a distinct epidemic during the months May to September inclusive. It was limited to 605 deaths, and of these deaths, in the same months, 521 took place in Kangra district. There are in this district 15 circles of registration, 8 of which returned deaths from cholera, and out of 651 villages in it 71 suffered. The cholera death-rate was 0·72 per 1,000 against a previous five years' average rate of 0·56. The only remark which the Sanitary Commissioner has been enabled to make on this outbreak is that the Civil Surgeon was unable to furnish a history of it. The case is, nevertheless, of great importance in epidemic history, and there can be little doubt that there were causes, very probably atmospheric causes among others, which determined the incidence of the disease.

10. Kangra district was not the only one attacked in the same region of the Punjab, for the epidemic showed its presence in Simla and Jullundur districts, in the former of which there were 24, and in the latter 25 deaths. These deaths took place during the same months as those in Kangra, as did also 17 deaths in Delhi. With the exception of a few detached single cases, it would be quite in consistence with the statistical facts to say that the cholera epidemic of 1884 took place within defined boundaries in a small area on the eastern hilly side of the Punjab, while the remainder of the province escaped.

11. We have no information as to the condition of attacked villages in Kangra. But in the Simla cases, some of them at least appear to have been connected with a marriage procession which passed through an epidemic region without any sanitary care. There were many thousands in the procession, which in some respects resembled an ordinary insanitary fair, and the medical officer who drew up the history tells us that the villages were very dirty.

12. The opinion expressed by the Civil Surgeon regarding the Delhi outbreak of 17 deaths is that the disease was imported, because travellers were seized, but this is not borne out by the facts, and requires no further notice.

13. *Small-pox* was a far more extensive and fatal epidemic than cholera. It covered more or less all the 32 registration districts. Deaths from it were returned from 334 out of 444 registration circles, and 4,232 villages out of 35,972 suffered. Deaths from it were returned from 38 towns out of 49. The village death-rate taken over the whole population was 0·86 per 1,000, and the town rate was 1·07 per 1,000. The severity of the disease varied greatly in different parts of the country, as is shown by the fact that in Shahpur the death-rate was 0·005 per 1,000, while in Kurnal it reached the very high rate of 4·20 per 1,000. This rate was exceeded in certain towns, in two of which, Umballa and Jagadhri, the rates were 5·77 and 5·87 per 1,000 respectively.

14. The deaths according to age stood as follows:—

	Total Deaths.
Under one year	4,713
One and under twelve	10,772
Adults	931

The registered monthly mortality was:—

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January	1,523	July	1,749
February	1,659	August	1,035
March	1,552	September	553
April	1,873	October	347
May	2,786	November	279
June	2,645	December	424

Reference to a previous table will show the relation of the small-pox epidemic to the epidemics of previous years, and we shall now show its relation to the vaccination service.

15. The staff for the official year 1884–85 consisted of—

Deputy Sanitary Commissioners	2
,, Superintendents of Vaccination	1
Native Supervisors	33
Vaccinators	280

And the year's work performed by this staff was,—

Successful primary vaccinations	537,951
,, re-vaccinations	6,542
Total	544,493

We have already given the registered births as 809,912, so that the successful primary vaccinations were a little more than five-eighths of the births. But, as a matter of fact, the successful primary vaccinations at ages under one year were 406,858, or, as near as may be, half the births. The ratios of vaccinations to deaths during the preceding five years have been as follows:—

Ratio of successful vaccinations per 1,000 of population	20·30
Deaths from small-pox per 1,000	1·14

If the population continued to live for the next half century without any addition by births, it would be by that time protected, and this merely shows how inadequate the work done is to the emergency. We are glad to know that of recent years the service has been greatly improved, and that the annual mortality table already given appears to show that good results have been already attained. But the practical result of all the past experience appears to be that, while the tendency of the disease to take on the epidemic character must be met by improving the sanitary condition of the people and of the localities they inhabit, the vaccination work must be more specially directed to protecting infantile ages, when most good may be done in the way of warding off attacks of the disease in after life.

16. *Fevers.*—The Sanitary Commissioner states that "more than two-thirds of the total mortality "were attributed to this cause." All the districts and all the towns suffered. In the districts, 436,260 fever deaths were registered, and 29,978 in the towns. The district fever-rate was 24·85 per 1,000, and the town rate 22·88 per 1,000. The fever death-rate for the whole province, town and country, was 24·71 per 1,000. No better proof of the universality of fever mortality in 1884 could be adduced than the fact that all the 444 circles of registration returned deaths, as did also 31,828 villages out of a total number of 35,972 in the province. A reference to the annual epidemic table already given will show that, with the single exception of the scarcity year 1879, the fever deaths registered in 1884 greatly exceeded those of any preceding year, while it also affords evidence that fever in the Punjab is becoming a more fatal disease than it was.

It is necessary, however, at the same time, to repeat what we have often said, that the diagnosis of fever is far from being trustworthy, while part of the augmented mortality may be due to improving registration.

17. The following abstract shows that fever mortality was high in all the months of 1884, but highest during the four last months of the year:—

Months.	Fever Deaths.	Months.	Fever Deaths.
January	23,829	July	21,500
February	23,564	August	24,384
March	22,437	September	45,530
April	22,227	October	164,761
May	28,509	November	76,985
June	25,546	December	47,384

If we could compare with certainty the fever-rates of different years, the result in 1884 would be unfavourable to the public health, for the previous five years' rate for the whole province, which had been 20·15 per 1,000, was represented in 1884 by a rate of 24·71 per 1,000. The death-rate varied greatly in different districts. The lowest rate of the year was 9·42 per 1,000 in Peshawar, but in 12

districts the fever-rate exceeded 20 per 1,000. The highest rates of the year were 45·12 per 1,000 in Umballa, and 52·95 per 1,000 in Ludhiana.

18. In attempting to trace the causes of this very fatal fever outbreak, the first point is to show what relation existed between the seasonal rainfall and the mortality from fever. As the first element is an average one, we shall place it alongside the fever deaths for the same months :—

	Rainfall. Inches.	Fever Deaths.
First quarter	2·8	67,830
Second quarter	3·8	76,582
Third quarter	19·4	92,014
Fourth quarter	0·9	229,136

It is clear from this abstract that the great fever mortality of the year followed the heavy rain of the third quarter. The figures, of course, include the whole country, but we can localize both the fever deaths and the rainfall, and by doing so we shall obtain a clearer view of the relation which existed between them.

19. For this purpose, we may select the examples of Peshawur, Umballa, and Ludhiana already given :—

Quarters.	Peshawur.		Umballa.		Ludhiana.	
	Rain Inches.	Fever Deaths.	Rain Inches.	Fever Deaths.	Rain Inches.	Fever Deaths.
1st	6·3	1,896	0·1	3,109	0·9	2,026
2nd	2·9	1,328	2·7	4,055	2·7	2,588
3rd	4·5	1,066	41·2	10,845	22·5	6,004
4th	0·1	1,791	1·9	30,160	1·1	22,149

This abstract shows very clearly the influence of rain distribution on fever. It may be taken for granted that all the local predisposing conditions remained much as usual, but, as a fact, fever increases very greatly with increase of rain, and this is shown even in Peshawur district, where the largest quarterly fever mortality followed so small a rainfall as 4½ inches in a quarter of a year. This result would appear to show that in all the cases cited some other agent was in action, and, in all probability, this was low and variable temperature. Any way, atmospheric causes are beyond our control, and we can only deal with a certain portion of their effects, and belonging to these are results of heavy rain, acting on undrained and water-logged ground, of which the following illustrations are given in the report. We shall first take Ludhiana district, with its fever death-rate of 52·95 per 1,000.

20. "In this district fever was evidently malarious, of the intermittent and remittent types. The "district of Ludhiana is partly situated along the banks of the river Sutlej, which bounds it on the "north-west, and the Sirhind Canal traverses it on the south-east; from these sources there is con-"siderable irrigation conducted over the surface of the country, and consequently the climate is "damper and more malarious than before. Besides these changes in the climate, it is the custom of "most of the natives, especially the poor, to sleep outside in the autumn months, and they thus "expose themselves to the unusual chills of the night air, and in most instances with very insufficient "clothing."

21. The fever death-rate of Umballa, as we have seen, was 45·12 per 1,000, and the following account of the district is given :—"Autumnal fevers of a severe and prostrating type prevailed after "the unusually heavy rainy season, producing excessive mortality. . . . . The disease "is attributed to the water-logging of the country, the standing crops preventing evaporation and "quick drying up of the soil, and helping to keep up the malaria." The only remark called for by the latter clause of this statement is that the amount of water supplied to the crops ought to be no more than is required for productiveness, and with a subsoil in the condition described there must necessarily be fever, and not only so but the vegetation will also suffer, and consequently the productiveness.

This Umballa fever was mainly due to the addition of large rainfall to an undrained country.

22. *Karnal*, with its district fever-rate of 40·38 per 1,000, and its enormous town fever death-rate of 70·42 per 1,000, affords a striking illustration of the influence of rainfall acting through local conditions. Its rainfall for the four quarters of 1884 was 0·5, 6·2, 32·6, and 1·5 inches respectively. Of this epidemic fever it is said that "its severity has been most marked in the city of Karnal, and "generally in the Karnal tahsil. The reasons are very obvious in the facts that it is in this portion "of the district the natural drainage of the country is so obstructed, and huge *jhils* produced by the "action of the old Western Jumna Canal. The state of Karnal city during the months of September "and October was deplorable indeed. Hardly an inhabitant, I suppose, escaped fever during the "epidemic, and death must have visited almost every family," says the Deputy Commissioner.

"The whole rural population of the canal country was more or less prostrated, and that even of "the dry tracts to the west suffered greatly. No mention of a great epidemic like this should be made "without referring to the chief cause of malaria, namely, the complete obstruction to drainage for miles

" and miles throughout the Karnal and Panipat tahsils by the old Western Jumna Canal and its " numerous watercourses which lie between the crest of the ridge on which the new canal runs and " the Jumna bed."

It is, however, satisfactory to learn that the subject was in the hands of the Irrigation Department for remedy.

23. The high fever death-rate in Delhi of 36·54 per 1,000 is attributed to the heavy rainfall of the middle half of the year, when all the rain, 42·2 inches in amount, except ·1 fell. "The parts of the " district most seriously affected were the canal-irrigated tracts and the parts adjacent to the " Najafgarh *jhil*." In the dry and mountainous parts of the district, where the wells are generally " sunk in the rock and are less liable to surface infiltration, the epidemic prevailed with less " severity."

24. In Ferozepore district, where the fever death-rate averaged 33·30 per 1,000, the parts which suffered most were those which have " within the last few years been brought under canal irrigation."

25. Other cases are mentioned in which, in the absence of irrigation works, the natural drainages of the country appeared to be insufficient to dispose of unusual rainfall, or where unusual rise of the rivers from rain probably backwatered the subsoil. One of these instances is Mooltan, which, although enjoying almost complete exemption from cholera, suffered greatly from fevers in 1884, and it is stated of the inhabitants of these portions near rivers that "scarcely a soul escaped." Great mortality occurred all over the country among children, and much disease was left among those who had passed through the fever.

26. No mention is made in the reports of the sanitary condition of affected population groups, but it may be taken for granted that this did not differ materially from the condition of preceding years. Intermittent fever is not a fatal disease in its simpler forms, and its death-rate may be safely assumed in part at least as indicating the sanitary state of dwellings and the localities which they occupy. But the main lesson taught by the facts is that in districts where paroxysmal fevers are always more or less present, and due to a damp malaria-generating condition of the country, the addition of irrigation water without drainage, obstructions of natural drainage by works, and added rainfall sufficient to water-log the subsoil over large areas may convert a simple fever into a highly dangerous epidemic.

27. The practical teaching of the year's experience is that more activity is required in improving the sanitary condition of villages, including the draining and general improvement of village sites, and that these district fever rates should be studied with reference to the influence of drainage defects on the public health, and the means of their removal, so far as this may be practicable. The impression produced by the facts as a whole appears to be that while the extent of fever prevalence was due to general causes, its severity of type and its fatality, as is the case generally, were mainly due to the insanitary conditions of inhabited villages and houses.

28. *Bowel complaints.*—The deaths under this head were 18,346, or in the ratio of 0·97 per 1,000, against a previous five years' average of 1·10 per 1,000. The mortality was generally diffused over the province, and was returned from 415 out of 444 circles of registration, but its incidence was local for all the deaths were registered in 4,179 village out of 35,972.

The bowel-complaint deaths, registered month by month, were as follows:—

Months.	Bowel Complaint Deaths.	Months.	Bowel Complaint Deaths.
January - - -	925	July - - -	1,134
February - -	799	August - - -	1,644
March - - -	833	September - -	2,068
April - - -	1,115	October - -	2,652
May - - -	1,527	November - -	2,481
June - - -	1,284	December - -	1,884

It is worthy of remark that the months of maximum mortality from bowel complaints corresponded with the months of maximum mortality from fevers.

29. *Injuries.*—Under this head were registered 128 suicides in males and 189 in females. There were 2,342 fatal accidents among males and 1,391 among females. Snake bites and wild beasts occasioned 758 deaths among males and 349 among females. The actual deaths from snake bites were 900 in 1884 against 1,189 in the previous year. All the districts returned deaths under this head. Simla returned only one snake-bite death, while Sealkote returned 72 and Gurjranwala 78.

Hydrophobia occasioned 158 deaths, and of deaths from wild beasts 10 were by jackals, 2 stings of scorpions, 7 by wolves, 6 by boars, 1 by a bear, and 6 by tigers.

All other causes.—Under this head were registered 153,854 deaths, but of this number the Sanitary Commissioner has assigned 32,916 as having been due to cough and chest diseases.

30. *Sanitary works (civil).*—Under this head it is stated that the drainage of the Dera Ghazi Khan cantonment was completed, or would be so early in 1885.

31. The water supply of Simla was expected to be completed at the date of the report. There are two reservoirs, one for two millions of gallons, the other for 1,180,000 gallons storage. The yield will be 4½ gallons per head per day for 16,000 people, and the cost has been 1,77,810 rupees.

The drainage of Simla was still incomplete, and the plan proposed for collecting the sewage at depôts and washing it down pipes to an outlet below the waterfalls had not been carried out as yet, and when completed, if it ever be so, it is satisfactory to learn that the Local Government cannot accept it as a permanent one. Would it not be worth while, instead of experimenting in a matter of this kind, to appropriate funds once for all to place the seat of Government beyond all risk permanently by removing the sewage to such a distance as to be out of harm's way, and to make the station a model of sanitary work?

32. The drainage works for relieving the subsoil of the city of Amritsar and its vicinity, including filling up of the town ditch, were making rapid progress towards completion. It is perhaps worthy of remark that this district and city, which suffered so greatly from fever a short time ago, proved to have been connected with a thoroughly water-logged condition of the country, had a fever-rate for the district of 20·82 against a previous five years' rate of 21·87 per 1,000, while the town fever-rate was 19·14 per 1,000, and this in the presence of the great fever epidemic of 1884.

33. Schemes for the drainage and water supply of Delhi had been prepared at Bradford under the superintendence of Mr. Binnie, and had been submitted to Government for approval. The water-works scheme had been approved at an estimated cost of Rs. 10,10,279. But the scheme of drainage, the estimate for which was Rs. 4,01,122, was still under consideration. No details of either scheme was given in the report. In the course of the year drainage works had been forwarded in the suburbs of Delhi.

34. Plans and estimates for the drainage of Hoshiarpur had been sent in to Government for sanction.

35. A project for a circular drain for the city of Sialkote had been sanctioned.

36. The drains and wells of Rawul Pindi had been repaired and cleaned, and a project for bringing water into the town from a distance of eight miles had been prepared.

37. The saucer drains for Peshawur had been completed, but the water-supply rests where it was.

38. These are the chief works of the year. But "from the annual reports received from the "district officers it appears that a great number of minor works, such as erection of latrines, "construction of roads, drains, and bridges, &c., were carried out in all the municipal towns of their "respective districts."

The expenditure on sanitary work of one kind or another in the 32 districts of the province stood as follows:—

	Rs.
Conservancy	4,28,297
Paving	60,592
Roads and bridges	1,39,759
Drainage and sewerage	91,908
Water-supply	1,22,678
Latrines	10,277
Other sanitary objects	18,726
	9,22,137

equal to 32 per cent. of the income.

39. It is satisfactory to learn that part of the outlay has been recovered in all the districts from the sale of manure.

The following have been the amounts received for the last five years:—

	Rs.	A.
1880	49,944	8
1881	18,785	8
1882	61,646	1
1883	68,968	3
1884	75,695	0

These figures show that there is a fund available for sanitary improvement which admits of large augmentation if a little attention be devoted to the matter.

40. *General remarks and personal proceedings.*—Under this head the Sanitary Commissioner informs us that, in the month of April 1884, the Local Self-Government Act was introduced into the Punjab, and that municipal committees and district boards were organised under the elective system, and all matters connected with local sanitation were vested in them as part of their work. In consequence of this administrative change the Sanitary Commissioner considered it to be advisable to visit all municipal towns, such of them, at least, as could be reached by railway (20 were visited), with the object of meeting the committees and impressing on them the importance of maintaining in full efficiency the various sanitary measures and regulations which had already been established. He met the committees and other leading people, and, after inspecting the locality, he addressed them on the public health subject, with special reference to the measures of improvement needed in the town. As Mr. Bellew is well acquainted with the nature of disease causes, and with the most practical method of dealing with them, it may not be out of place, for information, to give his views, very briefly, on what it is possible for the new local authorities to do.

He gives the first place to *cleansing*, as the most effective agent in protecting the public health; hence the necessity of organising and maintaining an efficienet conservancy staff in all towns. He impressed on them the fact "that it was owing to faulty and neglected scavenging that the breathing "air and drinking water of the towns were so generally and so seriously deteriorated and polluted "by impurities," and he showed that the foul matters which led to such results had everywhere a certain money value, amounting in the Punjab to 7,500*l.* for the past year. He called attention to the necessity of domestic and personal hygiene, to the bad condition of town drains, which were laid without any consistent plan, and had their outlets in festering pools of sewage all round the outskirts, while, under proper methods of draining, the sewage could be removed to a distance and utilized.

He states that in the Punjab towns most of the tanks and wells have been improved externally, but that further precautions are required for keeping out subsoil impurities. In our "suggestions" we showed the simplest means of effecting this result.

The sanitary condition of house compounds and houses is, however, of more vital importance to the public health of Indian towns and villages than mere surface cleansing, and until the municipal authorities can find means of including this duty along with others in their daily work, they must not expect much real improvement. So far as we can see, they have no power at present to deal with the matter. The Sanitary Commissioner has, however, fully appreciated the necessities of the case, and he has taken an important step at the initiation of the new authorities to keep them in the right groove. They can do this cleansing work at once; but, in all the towns, there are engineering works, many of them simple enough, which may, nevertheless, be so carried out as to endanger the public health, and it is in this direction that both work and money may be saved by acting under skilled advice.

We are glad to know that the Government of Bombay has foreseen this need by appointing a skilled sanitary engineer, whose services are placed at the disposal of the municipal authorities as adviser in such cases. It seems a necessary consequence of the new municipal law that each Government should follow this example, for there is no doubt that much bad work, and consequent useless expenditure, would be prevented by skilled guidance.

In conclusion, it will have been seen that the disease history of 1884 has proved anew the danger to public health of undrained country under the influence of rain distribution. But there is one hopeful case, if we can accept the Amritsar experience for a year as leading up to it, and this is that merely local drainage work, even in an undrained country, may save health and life, and the lesson from it should be that part of the duty of those new municipalities ought to include the efficient subsoil drainage of town and village sites as essential parts of their work. Mr. Bellew advocates, very properly, town and village improvements in streets, house construction, ventilation, &c., as of importance. But, at the commencement, at least, of so great an administrative change as has been initiated there should be sufficient inspection, to see that the new authorities exercise the important trust confided to them by their fellow-citizens to the public advantage.

12th March 1886.

No. 6.

Memorandum of the Army Sanitary Commission on the Report of the Sanitary Commissioner of the North-West Provinces and Oudh for 1884.

1. The population on which the vital statistics of the North-West Provinces and Oudh are calculated in this Report consisted of—

Males	22,912,556
Females	21,195,313
Total	44,107,869

The same population element has been made use of every successive year since the census year 1881, and if there has been any increase since that year, the ratios for 1884 will of course be too high.

2. The births registered in 1884 were, of—

Males	1,015,699
Females	915,262
Total	1,930,961

equal to a birth-rate of 43·77 per 1,000.

3. The deaths for the same population were, of—

Males	823,620
Females	731,722
Total	1,555,342

equal to a death-rate of 35·26 per 1,000.

Hence the registered births exceeded the registered deaths by 375,619, showing a gain of 8·51 per 1,000 for a single year.

4. The lowest registered birth-rate of the year was 22·92 per 1,000 in Dhera Dun. The highest was 58·58 per 1,000 in Lalitpur, but the results in these two cases appear to have been related to the small populations of these districts. Generally, the returns show good registering work done under this head, and in some cases, perhaps, too well done, unless there is some error in the population element, which is not unlikely.

5. The lowest registered death-rate of the year was registered in Dhera Dun. It was 19·99 per 1,000, and it may be contrasted with a rate of 57·31 per 1,000 in Hamirpur, which yielded the highest rate of the year. But diversities of death-rates are connected with local epidemics, which are more fatal in some districts than in others. The death-rates generally show better registration in 1884 than in previous years, but it does not follow from this fact that the public health was worse in that year, or that, in the case of births, more children were born. But it is a perfectly safe deduction to make, that the registering machinery in these provinces has been improving.

6. The following were the deaths registered under the usual heads in 1884:—

Diseases.	Total Deaths.	Deaths per 1,000 of Population.
Cholera - - - -	80,148	0·68
Small-pox - - - -	202,541	1·59
Fevers - - - -	1,074,097	24·35
Bowel complaints - - -	76,508	1·73
Injuries - - - -	21,107	0·48
All other causes - - -	150,946	3·42
All causes - - -	1,555,342	35·25

7. We shall notice briefly the information given in the Report under each of these heads, beginning with *cholera*. And, first, it will be observed that, with the exception of "injuries," cholera was the least fatal death cause of the year. Small-pox was above six-fold, and fever above 35-fold more fatal, and yet cholera was diffused over nearly the whole area of the provinces, for out of 49 districts all returned deaths except five. Its manner of distribution may be further understood from the fact that, although thus covering nearly the whole area of the provinces, cholera deaths were returned from 653 registration circles out of 1,146, and all the deaths took place in 3,551 villages out of 105,421 within the affected area, and thus only about half the registration circles and about one village in 30 suffered. The cholera of 1884 was thus a universally diffused epidemic of low intensity, but, nevertheless, the attacked villages averaged nine deaths each. In this, as in similar cases, the death ratio when taken over the whole population is deceptive. The rate for 105,421 population groups was 0·68 per 1,000, but for the affected groups it may be estimated at about 20 per 1,000. This epidemic history, which is repeated every year in every Indian Government, includes the fundamental law of epidemics, namely, that, being present in any country, only a small number of the population groups suffer at the same time. There is no spreading from a centre to cover a larger neighbouring area. Only a certain number suffer, and then the shower falls elsewhere. In the course of a definite number of epidemic years, all may have furnished victims, but never all at the same time.

8. As we have seen in the present case, the 3,561 villages in which the epidemic cholera of 1884 showed its presence were scattered over nearly the whole area of the North-West Provinces and Oudh. But this widespread distribution of the disease is not inconsistent with another observed fact, namely, that although the distribution of epidemics may be general over a country, their severity may nevertheless be local. For example, in the present instance we have Saharanpur district with a population of 854,996, living in 1,605 villages and towns, only one of which furnished deaths, but these were 53 in number, out of a population of 22,116 in the town of Deoband. The cholera death-rate in this town was nearly 2½ per 1,000, while the rate in the remainder of the district was *nil*. At the other extreme we may place Hamirpur district, with a population of 492,858, in 735 groups, of which no fewer than 184 were attacked during the same epidemic, and the rate for the district as a whole was 6·13 per 1,000, the greatest of the year.

9. Related to this subject of epidemic distribution is a report by the Deputy Sanitary Commissioner on cholera in Banda district, in which an attempt is made to arrive at some explanation of certain apparently anomalous facts, which, as he observes, "would seem to indicate that, without local "inquiry, it is not safe to base deductions on the returns of large areas such as mortuary circles."

Banda contains a population of 670,912, inhabiting 1,166 localities, of which 181 were attacked by cholera in 1884. The death-rate from this cause was 2·32 per 1,000, against a previous five years' rate of 2·45 per 1,000. In this case certain circles were attacked in successive years, and one object of the inquiry appears to have been to examine whether the passage of pilgrims was connected with the successive cholera outbreaks. That pilgrims traversed the district is true enough, and it is also true that a number of them died of cholera, and, as a matter of course, in a district where cholera is always more or less present, there were deaths among the residents. But it does not follow that the residents died because of the pilgrims. The inquiry resulted in showing that 90 per cent. of the cases

took place in pilgrims who had arrived sick, and that the attacks of villages along pilgrim routes were subject to the same law of inconstancy in different years as other places. Thus the Deputy Sanitary Commissioner gives a table of 24 towns, lying along pilgrim routes and subject to this supposed risk, and the result is that, in 1882, the great Allahabad mela year, 13 towns had cholera and 11 had none. In 1883 there was cholera in 14 towns, and 10 escaped, and in 1884, 12 had cholera and 12 escaped. The result of this inquiry did not prove that the addition of pilgrims to unhealthy towns was a safe proceeding, for in the present state of Indian towns an added population of this kind is an added local disease cause, but it showed that the epidemic law, we have already stated, held good equally in cases where there were no pilgrims to increase the mortality.

10. The great practical lesson taught by both classes of facts is the same, and it is that the true safeguard in either case is to remove the localising epidemic causes, and at this point the report on Banda supplies us with facts of importance.

Sanitary notes are given on a number of towns and villages, and they all tell the same story of flagrant want of cleanliness, the presence of unwholesome trades in the centre of towns and villages, want of drainage, and bad and deficient water-supply, but the reporter very properly adds that he does not attribute the disease to the introduction of any *materies morbi*, but to "general contamina-"tion resulting from the passage into the well by surface and subsoil drainage of the filth recklessly "deposited in or about the inhabited site."

In one place, where 6 per cent. of the people died of cholera, the case was put by a resident Chamar as follows:—"Last year in the rains the water got bad, but now it had become sweet again, and the "people had commenced drinking it." In this instance the surroundings of the well were so foul that "the stench was well nigh unbearable." It is further stated, on the authority of the tahsildars and others, "that it is a common thing in the hot weather for the lower caste people to collect the remaining "dirty water in the nearly dried up tanks into holes dug for the purpose, and to draw their drinking "supply from thence. In many places so inadequate is the supply to the demand that people sleep "round the wells so as to anticipate others in obtaining their daily supply." Another very important local disease cause in villages built on hill slopes is the practice of using the barren ground above the village as a place of deposit for filth, and during the rains the foul matter is washed down to the village and its wells, to endanger the lives of the people. With such facts observed on the spot by competent officers, there is no room for dealing with the pilgrims except to advise them, for their own safety, to keep out of such places. The case, in fact, has passed out of the hands of the sanitary officer into those of the executive, with whom must rest the responsibility for the existence of such a state of matters. But this report has a further value in showing the supreme importance of making detailed sanitary inspections of epidemic localities instead of trusting to general impressions as to epidemic disease causes.

11. We shall return afterwards to the question of local sanitary condition as related to epidemics, and we may here introduce the monthly data for cholera in 1884, which stood as follows:—

Months.	Cholera Deaths.	Months.	Cholera Deaths.
January	108	July	3,340
February	34	August	6,734
March	102	September	5,655
April	1,124	October	3,273
May	3,628	November	790
June	5,117	December	182

There was thus a complete epidemic in these provinces. As already stated, the cholera death-rate for the whole province was 0·68 per 1,000, but for the towns it was 1·73 per 1,000.

12. *Small-pox.*—The mortality from small-pox in 1884 was a very different matter from the mortality from cholera. It was, in fact, a great epidemic visitation during which 202,541 people perished. There are records of deaths from this disease in the last 15 years, and the death-rate in 1884 was 4·5 per 1,000 of the inhabitants, by much the highest death-rate within the period. The culminating year of the preceding epidemic was the scarcity year 1878, during which the rate was 3·9 per 1,000. In 1880 the small-pox death-rate, 0·1 per 1,000, was the lowest recorded rate. In 1881 the rate was 0·3, in 1882 it was 0·6. In 1883 it had increased to 3·1, and in 1884 the great death-rate of 4·5 per 1,000 was reached.

13. Small-pox prevailed in all the 49 registration districts with two exceptions, Gharwál and Meerut. In two districts the rate was 0·1 per 1,000, which was the lowest, and in the following districts, where the disease was most severe, the mortality was very high:—

Districts.	Small pox Deaths per 1,000.
Gonda	19·35
Bahraich	19·16
Pártabgarh	18·18
Rae Bareli	13·76
Basti	11·81
Sultanpur	10·69

Besides these rates, there were 25 districts in which the rates were between 1 and 8·87 per 1·000, affording sufficient evidence of the extent and severity of the epidemic. The statistical exceptions already stated of Gharwál and Meerut were, however, only apparent, for there were 11 small-pox deaths registered in the former district and 27 in the latter, hence the epidemic of 1884 covered the entire area of the North-hWest Provinces and Oudh.

14. A further analysis of the facts shows that, out of 1,146 registration circles, 943 yielded small-pox deaths, and out of 105,421 villages, no fewer than 42,663, a very high proportion, suffered, as did also 82 towns out of 102. The death-rate for the towns was 2·18 per 1,000, and for the village populations 4·59 per 1,000. The town death-rates varied as much as those of the districts, but the greatest proportional mortality of the year was yielded by Tanda, a town of 16,594 inhabitants, in which there were 453 deaths from small-pox, equal to a rate of 27·29 per 1,000. This town yielded a death-rate of no less than 64 per 1,000 from all causes.

15. The monthly prevalence of small-pox was as follows:—

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January	10,607	July	12,847
February	15,055	August	3,718
March	32,452	September	1,085
April	50,506	October	503
May	48,185	November	373
June	25,633	December	625

This table shows a great epidemic outburst during the hot months, followed by rapid decline. But the epidemic had come over from the preceding year, as the facts show. Unfortunately there are no means of obtaining the ages of small-pox deaths, so that no relation can be established between the vaccination service of the year and the small-pox mortality, except very generally.

16. *Vaccination.*—From tables in the Report it appears that, during the last six years, the births in these provinces had amounted to a total of 9,784,696, while the successful vaccinations during the same period had been 3,577,106, or about a third of the births for all ages.

During the official year 1884–85 the vaccinations were as follows:—

Under one year	294,583
One and under six	233,608
Total of all ages	563,864

But the births registered in 1884 were 1,930,961, which number represents approximately the number available for vaccination at the time when its protective power is most useful, and it is not improbable that the very small ratio of about 15 per cent. of the numbers born who came under the charge of the vaccinator may afford a partial explanation of part of the great mortality of the year. But the facts already stated show conclusively that the small-pox of 1884 was one of the most severe epidemics on record, and by far the most severe in those provinces since deaths were registered. We are thus brought face to face with the fact that, notwithstanding the existence of an active vaccination service, small-pox swept over the provinces just as if there had been none. No doubt attacks and deaths had been prevented by the service, but it is clear that it has been incompetent to deal with the disease in its epidemic form, as the following list of vaccination officials will show:—

Superintendent General	1
Deputy Sanitary Commissioner of Circles	3
Deputy Superintendents	7
Native ,,	50
Vaccinators, 1st Class	279
,, 2nd ,,	331
Chaprasis and other servants	64
Total staff	785

As a matter of fact, the total vaccinations at all ages performed by this staff amounted to less than three times the number of deaths, and the operations under one year of age were not one and a half times the total deaths. These remarks are not intended to call into question the utility of vaccination. But in presence of the facts the question is a perfectly relevant one, namely, whether dependence can henceforth be placed on vaccination as a protection against a small-pox epidemic? The question of course answers itself. In ordinary years lives are no doubt saved, and lower small-pox death rates may be co-existent with numerous operations. But this and similar experience appears to show that the remedies, if such be available, will have to be extended beyond vaccination, and will have to deal with epidemic causes affecting localities and their inhabitants. If sanitary work be neglected, no more dependence against small-pox epidemics can be placed on vaccination than can be placed on quarantine against invasions of cholera. The true remedies lie elsewhere altogether.

17. *Fevers.*—As has been already stated, the deaths under this head amounted to 1,074,097, equal to a death-rate of 24·35 per 1,000. But, as has been long known, the classification rests on no scientific basis. All we know is that so many deaths were registered under this heading. The following monthly fever deaths were registered in 1884 :—

Months.	Deaths from Fevers.	Months.	Deaths from Fevers.
January - -	64,595	July - - -	66,311
February - -	59,006	August - - -	83,832
March - - -	70,288	September - -	103,342
April - - -	76,619	October - -	150,880
May - - -	84,428	November - -	133,285
June - - -	79,140	December - -	101,401

18. Fever deaths were registered in all the districts and in all the 1,146 registration circles, with only 25 exceptions. The number of attacked villages is not given in the returns, but, with such a distribution of the disease, it is probable that very few escaped. All the towns returned fever deaths. Their death-rate was 27·54 per 1,000, while that of the village population was 24·35 per 1,000. This rate was a shade lower than the previous five years' average, which was 25·54 per 1,000. The highest fever death-rate of the year, 45·47 per 1,000, was returned from Terai district. One of the irrigated districts, however, Saharanpur, had a rate of 48·28 per 1,000, exceeding the rate of the fever Terai itself.

19. There is nothing new to report on the fever etiology of 1884. As usually happens the irrigated districts with heavy rainfall always suffer severely. In 1884 the fever death-rate of 12 canal irrigated districts averaged 36·33 per 1,000, against a provincial rate of 24·35 per 1,000. The two agencies which appear to have contributed to this result are stated to have been raising the spring level many feet by canal irrigation, accompanied in 1884 by excessive rainfall, which was 10½ inches above the average.

Of course the local insanitary conditions to which these fevers owe so much of their fatality remained as they were usually, and we have in these facts a sufficient account of the year's fever causes. We have drawn attention to both causes and remedies year after year, and the fever causes are still as operative as ever.

20. *Bowel Complaints.*—Deaths attributed to these causes numbered 76,508, or 1·73 per 1,000 against a previous five years' average of 1·79 per 1,000. These diseases prevailed in all the districts, and in 1,076 circles of registration out of 1,146. The attacks appear not to have been returned by villages. Bowel complaint deaths were returned from all the towns with two or three exceptions, and the death-rate from them was 3·71 per 1,000, or double the district rate. Their monthly incidence was as follows :—

Months.	Bowel Complaint Deaths.	Months.	Bowel Complaint Deaths.
January - - -	4,060	July - - -	5,668
February - -	3,549	August - - -	8,998
March - - -	4,221	September - -	9,424
April - - -	5,353	October - -	9,548
May - - -	5,974	November - -	7,925
June - - -	5,867	December - -	5,891

The wet and variable months appear to have predisposed the people to bowel complaint attacks.

21. The epidemic history of the North-West Provinces and Oudh may be resumed briefly as follows. The epidemic death-rate was 31·35 per 1,000 in 1884, as against 29·61 per 1,000 as the previous five years' average rate. The death-rates from cholera, fevers, and bowel complaints were all under the average, but the small-pox death-rate was 3·41 per 1,000 above the average, and, being so, after clearing away the saving of life from these lower rates, it brought into the account an increase of the total epidemic rate of 1·74 per 1,000.

22. *Injuries.*—Under this head 21,167 deaths were registered, equal to a ratio of 0·48 per 1,000. Among them were 2,090 suicides, of which 1,546 were females. From wounds and accidents there were 12,924 deaths, and 6,093 from snake-bite and wild beasts. There has been a slight decrease under the last head.

23. *All other Causes.*—Of the 150,946 deaths entered under this head nothing except their registered numbers is known.

24. The disease history of 1884 is wound up by a very important and practically useful table showing the death-rates of the year from small-pox, fever, and cholera in each of the 1,146 circles of registration, together with the population in 1881 of each circle. This we must hope will in future be an annual table, and together with the preceding data it will always render available the facts of

each small area in the provinces for sanitary purposes. We learn from it the great differences which exist between adjoining population groups in their liability to epidemic attacks, and these differences, so far as they are tolerably constant and not merely accidental, are our safest guides to sanitary work. Taking the information as it stands for the year, we may gather from it the localities where vaccination of infants is incomplete, also those where drainage is not sufficient to counterbalance the effect of heavy rain, and the circles which in all probability are the most careless in the matter of cleansing. As a whole, the facts have an important bearing on the question of polluted village sites, and hence they show even now where work requires to be done for lessening the liability of the people to attacks of the whole epidemic tribe of diseases, and amongst them of small-pox which in an epidemic year escapes from the influence of vaccination alone, and occasions such results as we have described above. To complete the table and convert it into a sanitary picture of the whole provinces, it would be most useful, if found to be practicable, to give in two or three words the sanitary estimate of villages in each circle under "drainage," "water," "domestic cleansing," which would include what is wanted. To most people sanitary statistics alone do not afford sufficient information, notwithstanding the deplorable character of the facts in the present case which they set forth.

25. *Sanitary Works (Civil).*—This, which forms Section IX. of the Report, contains brief notes on the sanitary condition of municipal towns and districts, in reference to measures of improvement carried out in the course of the year. These notes refer to 83 localities, and are chiefly about surface drainage of the town sites, and in some cases on water-supply improvements, cleansing, filling up holes, &c. There is nothing in them specially calling for remark. But it may not be out of place by way of caution to call attention to the fact that the aggregate average town rate in 1884 was 42·47 per 1,000, while the average rate for the preceding five years was 39·35 per 1,000. Of the total rate of 1884, 2·18 per 1,000 was due to the small-pox epidemic. But deducting this latter rate the death ratios of 1884 were above the average.

26. Under the head of "*General Remarks*" Mr. Planck gives an account of his inspection and other work during the year, and as it is of importance to put on record any cases where work has been done, we may notice some of the reports briefly. We may first introduce the following general statement on this subject from the preceding Section IX.:—"During the year 1884 works of "sanitary improvement continued to be effected in almost every important centre of population, and "I have reason to think the increasing powers and the authority of the municipal and local authorities "is resulting in increased attention to and more effectual performance of those works so important to "the welfare of the people."

This is so far well, and allowance must be made for the recent origin of the authorities, and the new character of the works they have been called upon to perform.

27. As an example of an improving town, we may select Shahjehanpur, which has a population of 69,892, of which it is reported that "the open spaces of the town site are, as a rule, scrupulously "clean; tree shade abundant, a number of young trees recently planted along certain roads and in "certain market places. The houses of the main streets substantially built and comfortable "Thoroughfares metalled, drained, and lighted at night. Many of them lined with trees. They are "cleanly kept and in excellent repair. Town precincts fairly clean. Latrines, 41 in number, of "sheet-iron, on wooden frames, on small wheels run on rails, which border a trench on either side. "When the portion of the trench between the latrine has been sufficiently utilized, it is moved on "and the part filled with earth." These latrines, he says, "are beyond comparison the most satis-"factory of any existing in the province." The town site is surface drained to outfalls. "The "smaller town drains are flushed daily with water, collected from wells into masonry built tanks, "placed at the commencement of the drainage system in different places." The tank outflow is about the size of a gun barrel, and the result, he says, "is most satisfactory as regards purity of the "air of the towns." The final outfall is into rivers. "If this method of purifying the small drains "could be introduced into all cities and towns, it is absolutely certain that the existing unpleasant-"ness complained of in many of them would become a thing of the past." This may be true, but the public health might still suffer unless the whole domestic sewage were rigorously removed to a distance every day, and all cess-pits abolished. This measure is the real foundation of Indian sanitary improvement, to which all others are secondary. If a sensible nuisance alone is dealt with it is clear that real epidemic local causes which in most cases are not amenable to the senses, may be overlooked. The water-supply of Shahjehanpur is obtained from wells, and is reported "pure."

But the year's sanitary statistics appear to show some justification for this criticism as follows:—The district death-rate in 1884 was 34·62, against a previous five years' death-rate of 40·30 per 1,000, showing a reduction of about 6 per 1,000. Of the 1884 rate, 1·67 was due to cholera and 0·79 to small-pox. Let us now take Shahjehanpur town, the capital of the district, and we find that its five years' death-rate, which had been 33·61 per 1,000, was raised in 1884 to no less than 48·76 per 1,000, an excess of 15 per 1,000, and of the 1884 rate, 10·07 per 1,000 was due to cholera and 0·18 to small-pox. These facts show the need of statistical comparisons in judging of sanitary condition, and they also show that the sanitary condition of a town cannot be safely estimated from its mere surface appearances. The practical question suggested by the figures is simply this: Why was the death-rate from cholera in this town sixfold the rate of the district of which it is the capital? It would be consistent with past experience to anticipate the discovery of disease causes in and about the houses, and the subsoil on which they stand, potent enough to have localised cholera in the town to the excess shown by the statistics. In this case the dead are buried within the town limits.

28. *Lucknow* has a population of 239,773. Its sanitary improvements appear to be in a transition state. Part is well paved, and there are surface drains of an imperfect kind leading to stagnant nullahs. The chief object appears to have been the removal of surface water. After many centuries of occupation without drainage or proper cleansing, the whole subsoil has become polluted, so that the wells, with few exceptions, yield bad water, and the people have to obtain their supply outside town limits. "Surface cleanliness is well effected by a considerable company of public sweepers. A "great number of public latrines are in use, and are very carefully managed. As a rule, open "spaces between the houses are cleanly kept, but small bad smelling places may easily be found." Sewage "still stagnates in noisome ditches among the houses," and there is also a custom "of digging "pits in the site, for the attainment of earth required for building purposes, and afterwards filling "in the pits with sweepings, and the authorities even undertake to fill with sweepings any large "excavations which require levelling. As a result of all these sources of filthiness, the soil of "Lucknow site has become very impure." We shall next see what information the sanitary statistics afford as regarding the public health.

Lucknow district contains a population of 457,051. Its total death-rate in 1884 was 28·45 per 1,000, and its previous five years' average had been 31·24 per 1,000, so that the rate was improving. Lucknow town had a total death-rate of 40·96 per 1,000 in 1884, and a preceding five years' average of 43·89, so that the improving town is following the unimproving district at a considerable distance. The cholera mortality of the district was 0·26 and of the town 0·76 per 1,000, or threefold.

It is clear that the disease causes at Lucknow have not yet been reached by the existing sanitary procedure, and, if we might be allowed to make a suggestion, it would be that, as the case resembles similar cases in England, where much surface work had been done before the Public Health Act became law, with little effect, it would be advisable to have a thorough examination made of the whole area, and a consistent scheme prepared for ultimately improving the town, which, probably, would have to include, not only works of water-supply and drainage, but town improvements in streets, lanes, and houses.

29. *Mirzapur* city is another surface-clean town, of 85,362 inhabitants. "Tree shade is plentiful. ". . . . City has been much improved in recent years by the construction of an important "market-place. . . . Surface cleanliness fairly well effected, but collections of refuse were seen, "which could not be removed because about one-half of the conservancy carts are useless, being "out of repair. . . . . Several public latrines and urinals. . . . Surface drainage of the "public thoroughfares is effected by stone-made drains, into which the house drains open; therefore "sewage flows in them. . . . The drains are good, and the sewers apparently efficiently "constructed, but the outflow is almost nothing. It follows that, for a great portion of the year, the "impurities of all waste or refuse water remain in the city, and also much of solid impurity. . . . "Water-supply from wells, which are numerous and extremely fine." This town occupies what ought to be a healthy site, about 60 feet above the Ganges, and it is evident that work of a sanitary kind has been intended. But here we have the same result as in the Lucknow case, for Mirzapur district had a death-rate in 1884 of 27·54 per 1,000, and a previous five years' average of 28·41 per 1,000, while the town rate was 39·23 per 1,000, with a previous five years' average of 41·09.

30. We shall take one more case, the town of *Fyzabad*, which has a population of 38,828. It is stated that in this town "the main roads are wide, metalled, watered, and well lighted at night, "thoroughfares generally clean, town surrounded by carefully cultivated fields of potatoes, poppies, "or vegetables. Surface cleanliness satisfactory everywhere. In all, 32 public latrines are in use, "well built, and effectually managed on the dry-earth system." The sewage of these is sold to cultivators. There are the usual surface drains, which require improvement. "The sanitary condition "of Fyzabad is satisfactory," except the existing piecemeal system of drainage.

The statistical results to health stand as follow. Fyzabad district had a death-rate in 1884 of 25·67 per 1,000, and a previous five years' average of 28·74. Fyzabad town had a death-rate of 42·05 per 1,000 in 1884, and a previous five years' rate of 40·15 per 1,000. The cholera mortality of the town was nearly fourfold that of the district. In this same district is the town of Ajudhia, with a population of 14,643, which returned a death-rate in 1884 of no less than 88·80 per 1,000, against a preceding five years' rate of 87·35 per 1,000. Surely, if there ever was a case for removing the population or for an exhaustive inquiry and improvement, we have one here.

31. The practical result of these inspection reports, of which we have given a few as samples, is, of course, that mere surface work, whatever it may appear to the eye, is not only no test of real sanitary condition, but may be misleading, and they suggest that a competent sanitary engineer, to examine and advise improvements in these towns, as is now being done in Bombay, would be a very desirable addition to the sanitary organization of the provinces.

32. Appended to the Report of Mr. Planck are three reports of the Deputy Sanitary Commissioners of Circles, which contain a few points regarding the sanitary arrangements of their circles which may be noticed. The chief part of their work, besides supervising the vaccination service, was making sanitary inspections during their tours of duty, and advising the local authorities on the required improvements.

The general impression produced by their notes is the same as that which follows from the perusal of the Sanitary Commissioner's own Report, and this is that the need of sanitary improvement is being more and more recognized in the localities, that more work is being done, but that this is of a surface kind, leading to great visible change for the better in the outer aspect of many towns, but there are no facts adduced to show that the authorities have as yet gone deeper than the surface,

while there are facts presented by the death registration which show that wherever the death causes are, whether they be at the surface or in the subsoil itself, they have not yet been reached.

33. We shall first select a favourable example, in which the town is more healthy than the district. The Deputy Sanitary Commissioner informs us that "the city of *Meerut* still maintains its pre-"eminence in surface cleanliness and excellent conservancy arrangements." This benefit is attributed to the active personal exertions of the officials, who see that the work is done. The death-rate in Meerut in 1884 was 39·60 per 1,000, against a previous five years' rate of 35·83 per 1,000. But Meerut district rate was 43·82 per 1,000, with a previous five years' average of 46·08 per 1,000. The town has a population of 60,948, and good work had apparently been done, but it had the enormous fever death-rate of 32·63 per 1,000, and even this was below the district fever-rate, which was 41·69 per 1,000. The remedy required in this example, both for town and district, is drainage, and the facts show the need of discussing these local questions in presence of competent engineering officers. The object is, not to make a show of the facts, but to remove their causes.

34. Of *Agra* it is stated:—"The surface cleanliness of this large city everywhere satisfactory. "Good progress has been made in paving the principal streets with stone flags. This will effect "a great improvement, both in the appearance of the streets and in their sanitary condition. Street "drains, as a rule, dirty, in some cases blocked up with rubbish." There are numerous public latrines, but no dry earth used, "and the management is not satisfactory." The death-rate of Agra district in 1884 was 40·27 per 1,000, and during the previous five years it was 36·31 per 1,000; while the death-rate among 119,079 in Agra town in 1884 was 47·90, and this is a constant rate, as is shown by the previous five years' average, which was 47·54 per 1,000. Of this great rate 3·74 per 1,000 was due to cholera, against a corresponding rate of 0·68 per 1,000 for the district. The chief death cause, both in town and district, was fever.

35. One other illustration of a surface-clean town will be sufficient for our purpose.

Muttra.—This town has a population of 44,775. It is described as follows:—"Surface cleanliness "and drainage everywhere perfect. There is sufficient latrine accommodation of the open kind. ". . . They are kept fairly clean." Now, in 1884 the district death-rate of Muttra was 29·65 per 1,000, and its previous five years' rate 35·64 per 1,000. But Muttra town had the enormous rate of 83·30 per 1,000, with a previous five years' average of 49·22 per 1,000. To the great rate of 1884 cholera contributed 10·43 per 1,000, small-pox 3·28 per 1,000, and fever 42·66 per 1,000, while the district rate from cholera was 0·31, from small-pox 0·67, and from fever 25·93 per 1,000. Surely in this case we have an example of the effect of bad locality.

36. There is one other subject which requires notice, and this is the reappearance of mahamarri in Kumaun. We dealt with this disease formerly, and pointed out the means of prevention, and we shall give briefly the facts in the Report. The author, Dr. Richardson, says, from "personal "experience of typhus fever in Kumaun, I am perfectly satisfied that it is like typhus fever else-"where. Mahamarri is merely a malignant form of the disease. In whatever form it shows itself, "typhus fever is essentially one of the class of" filth "diseases."

It appears that the sanitary rules formerly issued for the prevention of mahamarri have been neglected, and that cattle are still housed under family sleeping-rooms, with a community of foul air between the room and the stable below the bed-room from floor openings. There is no room ventilation, and abundant filth. The excuse for housing cattle in houses in these hill districts is cold, but this is a separate question to be dealt with by itself, and can afford no excuse for the population being decimated by this most fatal, and, it may be added, this most easily preventible, form of typhus fever. We desire to draw special attention to this matter. In this case the cause of disease is well known; rules for its prevention were laid down many years ago with beneficial result; and now from relaxed observance of those rules the evil is beginning again to prevail.

In conclusion, this Sanitary Report, besides its value as a record of the year's facts and experience, has also a negative value, for it shows exactly where the work done during the year has failed up to a certain point; it has done good, no doubt, but, beyond this, it appears to have exerted little protective influence during an epidemic year. It follows that in large towns, where the subsoil has become dangerously polluted by long neglect, the people are living in a state of health which at any moment may give way under the first breath of an epidemic, and great loss of life may ensue. In the present case, the great small-pox epidemic ravaged the provinces in spite of the persistent efforts of the vaccination service, and it may be well once for all to recognize that what may be called "epidemicity"—a condition of these zymotic diseases which may show itself at any moment—is connected directly with the conditions under which the people live, and that, when it has once shown itself, the penalty of past sanitary neglect is certain to be exacted in spite of all palliative measures.

It will be learned from what has been said that only a very small number of population groups have been brought under municipal government, while the result of their work in the present Report shows that mere surface improvements may leave the real epidemic causes as active as ever. The Sanitary Commissioner of these provinces has done apparently all that careful inspection and reporting could do to expose the evils, but there has been an absence of the skilled sanitary engineering element to examine and point out the required works and measures. And besides this, the real epidemic problems do not lie within the circles of a hundred towns or so, but they are to be found among the 105,421 villages in which the people spend their lives.

The Government of India has pointed out the real administrative defects in the present procedure in the following passage in their letter on this Report. They say, "No important steps appear to "have been taken to improve the sanitary condition of the villages in any district. The Lieutenant "Governor has, however, desired district officers to endeavour to induce villagers to adopt some "simple rules of sanitation. In towns with few exceptions no sanitary work of any magnitude "was executed during the year, the expenditure in most instances having been directed towards the "maintenance or improvement of existing arrangements in connection with drainage or water-supply, "and in some cases to small original works, such as sinking of wells, construction of masonry drains, "culverts, latrines, &c."

We have only to add that the village population, which forms the subject of the first paragraph of this extract, amounts to 41,358,922, and the town population to 2,748,947. The simple figures show the immensity and difficulties of the problems to be solved. But, unfortunately these epidemic outbreaks do not wait for solutions. They follow the law of their existence, and so long as resting places are left for them, they will be certain to find them.

16th March 1886.

No. 7.

Memorandum of the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Central Provinces for 1884.

1. The census population of these provinces in 1881 was returned at 8,817,185, and this number is used in the present Report for calculating the ratios. In a former Memorandum we took exception to this part of the Report on account of certain anomalous results presented by the ratios of successive years, and as our remarks have been referred to by the Sanitary Commissioner, we shall quote what he says on the subject:—

"In their Memorandum of the Report of the Sanitary Commissioner of the Central Provinces for "1882, the Army Sanitary Commission made the following remarks:—'In the ten years' interval "'1872 to 1881, it does not appear that any annual estimate of the population was used in calcu-"'lating the ratios, and hence it would scarcely be worth the trouble to compare the death-rates of "'1882 with those of preceding years, were it not that no other data are available.'

"The Commission would thus seem to hint that an annual estimate of the population on which to "calculate the ratios should be made as is done in England. But I believe from an examination of "the reports that no such calculation is made by the Sanitary Commissioners with the Government "of India or other Sanitary Commissioners in this country; and the experience of the year 1884 "with its comparatively large birth and small death rate, and the frequent recurrence of cholera "epidemics, appear to me to show how difficult it would be to fix any such estimate for the Central "Provinces."

2. We agree with what is here said about the difficulty of forming an annual estimate of population, especially in a country where registration of births and deaths has been recently introduced. What we are concerned with is that those charged with sanitary work and the expenditure of money upon it should have the means of estimating the effect produced annually, at least, by the outlay.

3. Methods of estimating increase of population over so large an area as India would probably vary, and movements of population would have to be taken into account, and of these the Central Provinces have afforded some notable examples, but, nevertheless, a careful analysis of the vital statistics of past years would enable an approximate value to be given to annual increase, subject of course to corrections until the normal law of increase was ascertained. As the matter stands at present we have the birth and death rates calculated on the first year of each decennial census period, and as this is done for all the districts, the ratios are unreliable and admit of no approximate annual or district comparisons. It is different, of course, with the actual numbers of births and deaths, which in the present state of the registration afford the most reliable means of estimating the state of the public health in localities and years. With these remarks we must leave the question in the hands of the authorities, who are fully aware of the importance of vital statistics to sanitary administration and progress.

4. The births registered in the Central Provinces in 1884 numbered 368,086, or 41·75 per 1,000 of the population. Compared with the numbers in 1881, the census year, which were 362,744, there was an increase in 1884 of 5,342 births, or ·54 per 1,000, both ratios being calculated on the population of 1881. Of the births in 1884 there were 190,702 of males and 177,384 of females.

The birth-rate is apparently too high from defect in the population element, but the numbers show good registration work. There was also a nearer approach to uniformity in the birth registration of the districts, which ranged between 33·37 and 51·21 per 1,000, but this latter ratio and several other district ratios go to show that the population element used was too low.

5. The deaths registered were of males 128,365, and of females 112,349, together 240,714, or 27·30 per 1,000 of the population of 1881. In 1881 the death-rate was 27·43 per 1,000. The lowest district rate registered in 1884 was 22·13 per 1,000 at Sambalpur, and the highest 32·70 was returned from Damoh. Generally the death registration is increasing in efficiency.

6. The death causes were as follow:—

Diseases.	Total Deaths.	Deaths per 1,000.
Cholera	142	0·02
Small-pox	4,882	0·55
Fever	145,342	16·48
Bowel complaints	21,991	2·49
Injuries	4,446	0·51
Other causes	63,904	7·25
All causes	240,714	27·30

7. The first remark suggested by this table is the very low death-rate from cholera. It was the next lowest on record, but this fact only shows that 1884 was a year of cholera quiescence in these provinces, and that it was part of the usual cholera history, which, for the last 11 years, has stood as follows:—

Years.	Deaths from Cholera.	Years.	Deaths from Cholera.
1874	14	1880	330
1875	24,643	1881	9,140
1876	20,124	1882	11,932
1877	3,418	1883	16,235
1878	40,985	1884	142
1879	27,575		

Nothing can be predicated from the low rate of 1884, except that it affords no evidence that less vigilance in dealing with local causes is required than has been necessary heretofore. Next year's death-rate may be that of an epidemic, instead of being due to a few sporadic outbreaks, as it was in the year 1884. Deaths were returned from no more than 14 registration circles out of 168. There are 27,647 villages in the provinces, all of which escaped except 40. There are 73 towns, six of which yielded 18 deaths, equal to a rate of ·02 of the town population, and the village death-rate was exactly the same.

8. The monthly incidence of the disease was as follows:—

Months. 1884.	Cholera Deaths.	Months. 1884.	Cholera Deaths.
January	—	July	1
February	—	August	—
March	52	September	12
April	16	October	28
May	17	November	17
June	5	December	1

Cholera was most prevalent in Nimar district, where four circles out of six, and 23 villages out of 470, yielded 84 deaths, or ·55 per 1,000 of the district population. The town which suffered most was Narsingpur, where, out of 10,222 people, five died of cholera, or ·49 per 1,000.

9. The Report contains no sanitary information about attacked localities. We are told that "the "outbreaks in Jubbulpore, Narsinghpur, Nimar, and Chanda are fully reported on by the Civil "Surgeons," but none of the reports are given either entire or in abstract. This is to be regretted, because amongst other results it breaks the continuity of cholera history, not only in the provinces as a whole, but in such cases as the appearance of cholera at Birman fair, a matter of very considerable importance. Not much can be learned from such a note as the following about Nimar, where the cholera was prevalent:—"Many marriage parties were moving about the country, and the "sanitary state of several of the villages in which persons were attacked is reported to have been "very bad."

10. *Small-pox.*—Information about small-pox is as deficient as that about cholera. It is statistical without giving conditions, while these last are daily becoming of more importance all over India, for the numbers of the vaccinated population increase without any corresponding decrease of mortality.

11. The following have been the registered small-pox deaths for the last five years:—

Years.	Small-pox Deaths.
1880	5,184
1881	1,816
1882	3,945
1883	4,696
1884	4,882
Total deaths	20,523

During the same five years there were 1,684,372 persons vaccinated. The successful vaccinations averaged 180·78 per 1,000 of the population, and the small-pox deaths 2·33 per 1,000, clearly showing that the remedy did not cover all the conditions of the disease. The above abstract indeed points to the progress of an epidemic in face of the vaccination. The maximum death-rate of the five years was returned from Nimar district. It reached a total of 5·45 per 1,000, and this district returned the highest vaccination ratio for the period of all the districts, namely, 245·16 per 1,000.

12. Small-pox deaths were returned in 1884 from 133 out of 168 registration circles, and from 2,001 villages out of 27,674. Every month yielded deaths, as the following abstract shows:—

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January	253	July	688
February	277	August	337
March	363	September	192
April	548	October	110
May	799	November	169
June	806	December	335

The towns, of which 42 were attacked, yielded 604 deaths, or ·80 per 1,000. The district rate was ·55 per 1,000.

13. The relation of small-pox mortality to vaccination may be approximately arrived at by the following comparisons. During five years ending 1884, the annual vaccinations averaged 336,874 per annum. The births in 1884 were 368,086, hence the vaccinations at all ages did not fall very far short of the births. The present Report does not give the ages of the vaccinated, but it gives the ages of deaths from small-pox as follows:—

Total deaths from small-pox	4,882
,, ,, under 1 year	1,968
,, ,, under 12 years	2,278

It follows that 40 per cent. of the small-pox mortality of 1884 took place in children under one year of age, a result which appears to show that too small a proportion of the children born was vaccinated within the year.

The actual numbers vaccinated in the Central Provinces has been so considerable that we may safely introduce the following yearly ratio of small-pox mortality as affording an estimate of the results to health:—

Years.	Small-pox Deaths per 1,000.	Years.	Small-pox Deaths per 1,000.
1870	·30	1878	2·18
1871	·20	1879	3·44
1872	·57	1880	·69
1873	1·37	1881	·21
1874	2·38	1882	·45
1875	2·78	1883	·53
1876	·51	1884	·55
1877	·37		

These figures appear to show what may be called a current death-rate from small-pox, into which periods of considerable epidemic increase are intercalated, but there has been no such increase during the last five years, although it can scarcely be said that the figures show steady decline in the mortality.

The whole experience may be summed up as follows:—A much larger proportion of children under one year of age should be vaccinated, because 40 per cent. of the mortality takes place under that age. The disease is liable to take on the epidemic character in these provinces as elsewhere, and this characteristic of the disease must be met by sanitary work.

14. *Fevers.*—There were registered 145,342 deaths from fever, a ratio of 16·48 per 1,000 of the population. The preceding five years' average rate had been 18·68 per 1,000. The disease, though less fatal, was generally diffused over the provinces. All the registration circles, 168 in number, returned fever deaths, and out of 27,674 villages 21,451 suffered. The fever type was of the ordinary intermittent form.

15. The following was the monthly mortality :—

Months.	Fever Deaths.	Months.	Fever Deaths.
January	11,271	July	8,859
February	9,655	August	12,289
March	10,918	September	15,858
April	11,342	October	15,254
May	11,694	November	13,199
June	10,855	December	12,646

All the 73 towns returned fever deaths, numbering in all 7,880, or 10·41 per 1,000 of the town population, while the rural rate was 17·05 per 1,000. The lowest district fever rate was that of Nagpur, 6·66 per 1,000. The highest, 25·28 per 1,000, was returned from Narsinghpur. The fever death-rate of Nagpur town was 3·41 per 1,000 out of its large population of 98,299. This was one of the towns which escaped cholera. The highest town rate of the year was returned from the small town of Mohari, where out of 5,142 people 164 died of fever, or above 3 per cent. of the population. But in the present state of fever diagnosis not much reliance can be placed on the figures; it may, however, be safely stated that there is some error in attributing so large a loss of life to intermittent fever.

16. The only remark bearing on the predisposing causes of these fevers is as follows:—"I think "that the low death-rate from fever is not what would (judging from the remarks in former sanitary "reports) have been anticipated considering the heavy rainfall that prevailed in the provinces" (to wit, 67·4 inches, against a previous 18 years' average of 49·83 inches). But the absolute quantity of rain is of less importance in such inquiries than its distribution in time and locality, and the officiating secretary to the Chief Commissioner states that the rainfall was above the average in the rainy months (July to October), and below the average in the hot weather months (March to June), hence the drying up was more limited in duration, and changes in temperature somewhat less severe.

Not much help can be got from this discussion as it stands, because a reference to the monthly mortality table shows that the registered deaths did not fall greatly in number after the rains; all that really can be said is that if the rains had ceased sooner the fever deaths might have been more numerous. No more need be said on the question of climate, because taken by itself it scarcely aids our work, while on all the other causes of fever there is a total blank in this Report. As part of the fever history of these provinces we may quote from the Acting Secretary's letter the following fever rates during the last ten years :—

Years.	Fever Deaths per 1,000.	Years.	Fever Deaths per 1000.
1875	16·28	1880	18·46
1876	20·22	1881	19·42
1877	17·70	1882	17·31
1878	29·50	1883	49·86
1879	18·34	1884	16·48

These figures show that with high annual rates the first and last years in the series exhibited exceptionally low rates, but this is all we can deduce from them.

17. *Bowel complaints.*—Under this head, which includes deaths from dysentery and diarrhœa, there were registered 21,991 deaths, or 2·49 per 1,000 of the population. Every one of the 168 circles of registration returned bowel complaint deaths, and 7,655 villages out of 27,674 did so.

18. Bowel complaints and cholera are about the best known diseases among the Native population, and considering the great disproportion between the mortality of these diseases in the returns, it is of interest to give the following monthly contrast for the year :—

Months.	Registered Deaths from Bowel Complaints.	Registered Deaths from Cholera.
January	1,478	—
February	1,155	—
March	1,380	53
April	1,653	16
May	1,653	17
June	1,471	5
July	1,485	1
August	2,465	—
September	3,905	12
October	2,421	28
November	2,112	17
December	1,813	1

It is evident that the data refer to two distinct diseases or more. Cholera apparently had to wait for the month of March before it could find a footing, and then it burst out with the largest monthly mortality of the year. So far as these diseases are related to local predisposing causes it is evident

that bowel complaints are more influenced by them than cholera. This is all that can be said, for the Report contains no information on epidemic death causes except what may be inferred from the details under the head of sanitary works.

19. *Injuries.*—Under this head were registered 293 suicides of males and 295 of females. There were 2,833 deaths from wounding and accident, 1,019 from snake-bite and wild beasts, in all 4,446 violent deaths.

20. *All other causes* included 63,904 registered deaths, of which nothing besides the number is known.

21. (*Sanitary Works Civil*). There are returns of income and expenditure given for 19 head-quarter towns, from which it appears that their total income is about 63,000*l.*, which was expended on public health work in very various proportions. Including medical relief, the lowest percentage of income so spent was 11·76 in Bilaspur, the highest 74·60 in Balaghat. Generally, the largest proportion was devoted to conservancy. In the course of the year 144 new wells were dug and seven were repaired. These numbers are exclusive of the usual repairing work. A new pumping engine was put up for water-supply in Nimar. In Balaghat four swamps were drained. These, with the drainage of some land close to the town of Bhandara and the construction of a few latrines and dust bins, were the chief works of the year. The annual death-rate taken over the 73 towns was 25·37 per 1,000, against a previous five years' rate of 35·40, but the lower rate was mainly due to the absence of cholera, from which only 18 deaths took place in all the towns.

22. *General remarks.*—Section X., which gives some account of the sanitary proceedings of the year, is by far the most important part of the Sanitary Commissioner's Report, for it shows that a considerable number of simple but efficient improvements were in progress. He personally inspected 18 of the towns and a considerable number of villages, with the object of estimating their present sanitary condition and the progress made in applying legal provisions to the removal of disease causes. Brief abstracts are also given of inspection reports made by Civil Surgeons.

23. The details need not be given in full, but the following brief abstract will show the general nature of them:—"In all the towns a large amount of attention is paid to sanitation. . . . In "all but Balaghat and Badnur, which are really villages, public latrines exist, and the dry-earth "conservancy system is in force."

24. On the subject of *drainage* the information is not so satisfactory.

Of *Bhandara* we are told that the drainage is defective; the outlet is a natural one, liable to being silted up, and pools remain after the rains. "Shallow tanks exist on the outskirts of the town, and "pits caused by the digging of clay for making brick and tiles, the brickmakers being allowed to dig "it where they please." This is a common disease cause all over India. It should be put an end to, and the holes filled up. An instance is mentioned in the Bengal Report of the present year 1884, in which clay is taken, not from pits, but from the surface. Anyway, pit digging is most unsafe near any town or village.

At *Seoni* a contrary proceeding is taking place, for we are told that "very good work has been "done in the way of filling up some hollows and draining others." Now, either the digging of holes or the filling up must be immaterial to health. It should be decided which practice is to be followed by the municipalities and village authorities, and if digging is to be prevented, as beyond all doubt it ought to be, it should be done. In the present case drainage is being steadily improved by shallow surface drains. At Hinganhat the drains are badly constructed and much covered up by boards or masonry. No drains exist except along the main roads.

At *Nagpur* the drainage is "defective. There are a large number of more or less deep excava-"tions scattered through all the inhabited site, in a large part of which no drains exist." Nagpur was one of the first towns which brought in a water-supply, and the expense of this work has not yet been cleared off. The municipality is thus hampered from want of funds, but, unfortunately, water cannot be had without drainage to carry the used water away except at a great risk to health. Nevertheless, the statistics show improving health. The rate from all causes in 1884 was 23·95 per 1,000, against a previous five years' mortality of 30·15 per 1,000. It had no cholera, and the fever deaths were 3·41 per 1,000. Besides the current conservancy work, Nagpur will derive most benefit by extending the water-supply over the town, by abolishing all bad and doubtful wells, and by adopting a system of drainage suitable to the locality.

Of *Warora*, it is said that its drainage, "except that of the chief bazaar, is very bad." The town stands in almost a swamp in the rains.

A similar remark is made about the drainage of *Chanda*.

Jubbulpore, where the conservancy is well carried out, has defective drainage. "A large part of "the city has no drains, while there are hollows and excavations which it would be well to fill up, if "possible."

These instances appear to be sufficient to show the nature of the present defects, which the Sanitary Commissioner sums up under the expression "that the drainage of most towns is unsatisfactory." And he suggests that the first thing to do is to have a series of levels taken all over the towns, and then shallow drains constructed on these levels, instead of the present deep drains, which are receptacles of rubbish, and very often without a proper fall, from having been constructed piece-meal. This would appear to be the proper course to follow, but it must be borne in mind that no system of surface drains, however well laid, can obviate the necessity of very frequent washing out by special provision of water, in the way already in use in a number of towns in the north of India, where water is raised from wells into tanks at the higher ends of the drains, whence it is discharged into those to wash their contents to the outlet. In this way nuisance and unwholesome emanations are prevented.

25. *Water-supply.*—We have already noticed the increase of wells, and a few points may be introduced from the digests. The water-supply of *Bhandara* is almost entirely from wells. Many of the town wells are brackish, while those outside the town are good, marking, apparently, sewage pollution of the town wells.

The *Seoni* wells are also brackish, but the domestic water-supply is mostly drawn from a filtered tank supply, which is, of course, a great improvement; but the water, in place of being properly distributed, is drawn from the reservoir, "into which all kinds of vessels and ropes, clean and dirty, "are dipped, and into which all kinds of impurities must be blown by the winds." This practice is altogether contrary to the true principles of water distribution, which render it imperative that the water should reach the consumers as pure as it is at its source. What is wanted in the present case is the delivery of the filtered water into a closed tank, sufficiently raised to admit of water being drawn from it by water taps.

The wells at *Narsinghpur Kandela* are mostly out of repair, and yield brackish water, an almost certain proof of sewage reaching the wells.

A similar condition of the water-supply exists at *Chindwara*. The best wells are those supplied by infiltration from a tank, one of the methods of obtaining better water proposed in our "Suggestions."

Hinganghat derives its water-supply for the new town by pipes from the river.

At *Nagpur* the water-supply from the Ambajhorri lake "is being steadily extended," but is still incompletely distributed.

For some cause not stated the town of *Chanda* is being "steadily deserted." Much of the site has become overgrown with jungle, and the people are settling in villages. The well water is brackish and impure. *Jubbulpore* has a water-supply conducted into the town, and this is largely distributed by standards.

The water-supply of *Damoh* is derived from a gathering ground and receiving tank. The water is coloured, and should be filtered before distribution.

Raipur has its water-supply largely from tanks. "The purity of the water appears very doubtful." This is one of the largest towns in the Central Provinces, and contains 24,948 inhabitants. Its five years' annual death-rate had been 34·38 per 1,000, and in 1884, in the total absence of cholera, it was 32·75 per 1,000. The suspicious water was there, but not the cholera. But of the 1884 death-rate no less than 24·21 per 1,000 was due to "fevers." In this case the tank water should be examined, and steps taken by filtration and protection to improve the water.

Defects in the water-supply of *Burhanpur* are described as follows:—"Water-supply is from the "spring, some three miles off. The water from this has not been laid on to all parts of the town. "The system of building reservoirs instead of or in addition to standards appears bad, as the water "in them is open to pollution from many sources." Proceedings such as these are contrary to the first principles of water distribution, which, as we have already stated, require that the supply should be delivered for consumption as pure as it leaves the source. In such cases as this open tanks should not be constructed within town areas, and tanks in towns are only of use as distributing centres from which water is to be taken, never by indiscriminate drawing, but from water taps let into the tank.

Khandwa appears to be supplied with water by pipes from a bunded nullah, which derives its supply in turn from a catchment area "not attended to as it should be." The supply of this town is still undecided, and under consideration for extension.

26. There appears to be no example in these provinces of the application of liquid sewage to agriculture, for there is no house drainage. Removal of all filth and refuse matters by hand labour is more or less practised, together with trenching and cultivating the trenched area. This, if carefully supervised, is the next best method after sewage irrigation, but it requires care and continual oversight to prevent fouling of surfaces and pollution of subsoil water sources.

27. It is satisfactory to learn that a commencement has been made in the sanitation of part of the 27,674 villages in the provinces. What has been already stated refers only to sanitary work in a few towns, but as the real epidemic disease causes are found in villages and their vicinity, it is clear that until these disease centres are dealt with the public health can never be safe. The method in use for dealing with village problems has been to draw up and circulate sanitary rules, which, besides being of the nature of positive enactments, contain a certain amount of instructional matter to enable the local village officials to understand what is required of them. The rules include removal of all house refuse matter outside the area; filling up of holes and providing rain-water drains to be periodically cleared out; the use of house refuse after removal and keeping for manure; providing latrines, and prevention of personal nuisances within 200 yards of the boundary; rooting up useless bushes, high grass, &c., within 100 yards of the boundary; providing properly constructed wells, and protecting the outskirts of water-supply sources along rivers from pollution; burying of carcases of animals not nearer than 300 yards to leeward of villages; burning or burial of human remains to be carried out at a distance; cautions against using foul village tanks as water sources, and proposing wells sunk near them as safer sources.

28. All these prescriptions are good, and, if obeyed continuously, will no doubt remove many disease causes. But they contain no provision for doing away with the great Indian village evil of stalling cattle in houses or house compounds. Just as it may be possible to supply a whole village except the low castes with water from a single deep well, so it might be possible to plan some kind of arrangement whereby the village cattle might be sheltered and protected within the boundary, instead of risking the health and life of so many people as is entailed by the existing practice.

The present arrangements are very properly designated by the Sanitary Commissioner as "a very "insanitary practice, especially as these cattle sheds are usually in a most foul condition, and is one

"that it is most desirable to put a stop to." Anyway a beginning has been made, and we have a few statements by the Sanitary Commissioner to show how the rules have been applied, this inspection and report being part of the procedure.

Of the *Saugor* district he says,—"Much attention is given to the sanitation of the head-quarter "towns or tahsils, and to that of villages, the result being that in it I found the rules regarding the "depositing of refuse outside the villages, and the using of a selected site as a latrine more generally "carried out than in any of the other districts through which I passed." But in most of the villages these rules appear not to have been carried out.

The rules in regard to burial were "more or less in force."

Improved water-supply is said to be "fairly well carried out," or "not unfrequently followed for "the supply of the upper classes."

We are glad to learn that in *Nimar* the Civil Surgeon has given much attention to the providing wells for the lower castes, "a very good sanitary work."

29. The abstract of inspection works by Civil Surgeons contains information similar to that already given, and no remark is called for.

30. *Fairs.*—We have already noticed the appearance of cholera at Birman fair, held in Narsinghpur district. The district had in all 11 deaths from cholera in four villages out of 336.

Birman fair was held between the 13th and 22nd November, and 35,000 people were present on the great bathing day. There were five cases among pilgrims at the fair, and eight were attacked after leaving it. There were four deaths.

Ramtek fair was attended by about 234,000 people, and there was no cholera. The usual sanitary work was done in both cases.

31. In conclusion, instead of making any general remarks of our own on this year's Report, we prefer to give the following summing up by the Chief Commissioner, with which we would express our general concurrence. He says he "is quite aware that much has been done in improving the "sanitation of towns and villages. He has insisted, when necessary, on municipal committees doing "their duty in this matter, and he will not permit this duty to be neglected. But he also realizes "that much good work has been done, and he is convinced that to have such work carefully "ascertained and acknowledged does much to encourage those who are engaged in it. In regard to "village sanitation energy must be accompanied with patience, but greater progress may no doubt "be looked for now that we have responsible mukaddams in every village, and that the agency of "local boards can be made use of." We would only add that the true test of sanitary progress in the Central Provinces, as elsewhere in India, is to be found only in the gradual decline of mortality from epidemic diseases. And whenever in any locality the epidemic deaths have been more numerous than usual there, the sanitary executive should be at once called to account.

15th June 1886.

No. 8.

Memorandum of the Army Sanitary Commission on the Report of the Sanitary Commissioner for the Hyderabad Assigned Districts for 1884.

1. The population adopted in the present Report is that of the census of 1881, namely 2,630,018. In 1884 the births registered were of males 56,143, and of females 52,582, making a total of 108,725, or 41·3 per 1,000 of the census population. The registration appears to be improving in this datum, for the lowest rate registered was 37 per 1,000 in Wun district, and the highest 45 per 1,000 in Buldana, but some correction for increase of population appears to be required. The ratio of male to female births was 106·8 to 100.

2. The registered deaths were—

Of males	33,899	
Of females	30,909	
Together	64,808,	or 24·6 per 1,000.

For every 100 deaths of females there died 109·7 males.

As compared with the previous five years' death rates, the mean rates for these years were 29·8 for both sexes, showing a reduction in the death rate of 1884 of 5·2 per 1000. This reduction extended to all the six districts of the province.

3. The assigned death causes in 1884 were as follow:—

Diseases.	Total Deaths.	Deaths per 1,000 of Population.
Cholera	87	·03
Small-pox	615	·2
Fevers	30,551	11·6
Bowel complaints	9,319	3·5
Injuries	959	·4
All other causes	23,377	8·9
Total	64,808	24·63

It will be seen from this abstract that the causes of death of about a third of the mortality were not registered; that cholera was the least fatal epidemic, and diseases classed as fevers the most fatal death causes of the year.

4. The cholera history in these districts presents features of great interest, from the immense variations in mortality which it presents in successive years. Who could have anticipated, for example, that these 87 deaths in 1884 had been preceded in 1883 by a loss of 27,897 deaths from cholera? The sequence was, however, only an example of what usually takes place, as may be seen in the following abstract of cholera mortality for a series of 17 years, beginning with 1868, in which year cholera yielded 5,447 deaths.

The mortality in subsequent years of the series was as follows:—

Years.	Deaths from Cholera.	Years.	Deaths from Cholera.
1869	10,947	1877	842
1870	504	1878	34,806
1871	581	1879	223
1872	1,578	1880	1
1873	—	1881	5,404
1874	2	1882	3,576
1875	22,465	1883	27,897
1876	2,683	1884	87

The average mortality for the first 16 years was 7,152 deaths, represented by 87 deaths in 1884.

5. The cholera of 1884 had none of the usual features of an epidemic. There was an outbreak in Buldana district in May, during which there were 5 deaths; the same district yielded 8 deaths in September, 25 in October, and 13 in November. These deaths, together with 6 in Ellichpur district in September and 30 in Akola in November, made up the year's mortality, which stood as follows by months:—

	Deaths.
May	5
September	14
October	25
November	43
Total	87

6. There are 143 registration circles, 10 of which yielded cholera deaths. Eleven towns, with a population of 15,177, returned 11 deaths, or 0·6 per 1,000 on the town populations, but 10 of the deaths were registered in one town, Malkapur, with 8,152 inhabitants, a death-rate of 1·2 per 1,000. The remaining 76 deaths were returned from the six districts, giving a death-rate of ·03 on their entire population of 2,491,640. But this population is distributed among 5,501 villages, only 19 of which were, however, affected. The deaths hence averaged 4 per attacked village.

7. Taking the past cholera district as a whole, it has presented phenomena of which no explanation has yet been given. The case as against any single cause for them as regards the experience of 1884 is put by the Sanitary Commissioner as follows, and we quote it here in order that it may be duly weighed elsewhere:—"These variations in the intensity of cholera outbreaks from year to year occur "everywhere in India, ... and would indicate that something beyond the cholera bacillus "contaminated water supply, or human intercourse is necessary to explain this difference between the "results of different years. If any of these theories regarding the cause and spread of cholera be "true, how came it that cholera did not spread from these 19 centres by the diffusion of the cholera "in some one of these ways, instead of remaining localized in the manner it did?"

After showing that similar defects prevail in all other attempts at explanation, he continues:—"Whatever these conditions or influences may be which originate and favour the spread of cholera, "they still remain to be discovered, or the cause explained why one season should be healthy and "another unhealthy."

8. But the case is different when practical measures of mitigation or prevention have to be considered, and he says on this all-important aspect of the question, "We know, however, that much "can be done beforehand to ward off the ravages of cholera when it does come by attention to the "sanitary condition of our towns and villages, for experience has shown that as dirt invites and "fosters cholera, so on the other hand a good sanitary state greatly lessens the liability to attack."

This is about all that can be said in the present state of our knowledge. All the facts point to epidemic intensity as being the factor which determines the extent of prevalence and tendency to attack in any given season, but the actual severity and mortality of cholera is very materially influenced by the conditions of life of the people. And it so happens that these conditions are greatly under our control, yet they are the very elements of the question, which are liable to be overlooked or ignored when attempts are made to simplify or systematize our knowledge of cholera by assigning its manifold phenomena to a single hypothetical cause.

9. Recent European experience has afforded abundant evidence of this result, more especially in the case of Spain, where one of the most fatal cholera epidemics on record has been connected with very obvious neglect of the simplest sanitary laws, and where immunity from the consequences was fruitlessly sought primarily in quarantine, and then, when quarantine had failed, by inoculating some 50,000 people with a preparation of the so-called cholera bacillus. The real result of the proceedings having been to confirm the views of those who held the non-contagious nature of cholera, and not to obtain immunity from attacks of cholera by restrictions on intercourse, or by submitting to the operation.

10. In a previous abstract we have shown the extraordinary variation in the cholera mortality of different years, and the following analysis shows the aggregate monthly cholera deaths for 10 years, 1875 to 1884, to which we have added the mean temperatures and mean rainfalls for the same months:—

Months.	Aggregate Monthly Deaths from Cholera, 1875 to 1884.	Means of Ten Years, 1875 to 1884.	
		Mean Temperature.	Mean Rainfall.
		°	Inches.
January	63	67·1	·37
February	2	75·4	·18
March	29	83·9	·23
April	137	87·3	·15
May	2,796	93·0	·48
June	11,892	86·0	6·46
July	31,072	79·6	8·62
August	32,984	79·0	7·35
September	9,918	78·8	7·76
October	2,368	76·2	2·39
November	801	71·2	·43
December	819	67·6	·84

The first result of this table is to show the extraordinary difference in the cholera death-rates of different months. May is the month of epidemic increase, August is the month of maximum mortality, and the mortality of the four months, June to September, was about 13-fold the mortality of the other eight months. But the really erratic nature of cholera in these provinces is shown by the annual monthly data. Thus, in January, the 63 deaths took place in five years, while five years escaped. In February the two deaths registered were in two years out of ten. In March all the 29 deaths were due to one year. In April three years suffered and seven years escaped. In May, when the epidemic began to increase in severity, seven years yielded deaths and three years none. The June increase took place in eight years, and in two there was no cholera, but in other two years there were only two deaths. In July and August, when the epidemic loss was greatest, one year only escaped loss in the former month and two in the latter. September, October, and November escaped deaths each during two years of the ten, and in December four years had no deaths.

11. On comparing the column of mortality with those of climate, it appears to be proved that low temperature is accompanied by decline of cholera, and that the great increase during the middle of the year is preceded and accompanied by increased heat and by increase of rain, which last, however, is followed by reduction in mortality, while the low fall of rain in the first five months is followed by the annual epidemic outburst. It is impossible to say whether these events are merely coincident, or whether they stand in the relation of effects and causes. Of the remarkable character of the facts themselves there can be no doubt, although they do not help us to account for the equally remarkable variations in cholera mortality which take place in successive years. There seems to be at present some missing link in the facts, but we must admit that the intensity and fatality of cholera in these provinces year by year is itself a fact in the epidemic history marking what may be called variation in epidemic intensity. It was at one time supposed to indicate that during the severe epidemic years so many susceptible people died that there were fewer left to yield next year's deaths, but the tables of which we have given abstracts do not confirm this view, and we must for the present turn our attention to the practical aspects of the question.

12. We have already stated generally the year's distribution of cholera, and the next table shows how the intensity of the disease varied in each district during two years, 1883 and 1884, as this is shown by the number of villages attacked, and the deaths in each.

Districts.	Total Number of Villages.		Number of Villages affected.		Average Number of Deaths in each affected Village.	
	1883.	1884.	1883.	1884.	1883.	1884.
Amraoti	1,047	1,047	408	—	15·5	—
Ellichpur	474	477	265	4	19·4	1·5
Wun	1,260	1,192	251	—	11·4	—
Basim	945	945	305	—	15·6	—
Akola	964	964	278	5	15·5	6·4
Buldana	874	876	286	10	19·4	5·1
Total	5,564	5,501	1,838	19	15·2	4

To complete the means of comparison which this table affords, we may repeat that the total deaths from cholera in 1883 were 27,897, and in 1884 they were 87. Nothing could more clearly show how little real knowledge we as yet possess of the determining causes of cholera epidemics. We have no reason to suppose that local, personal, or climatic conditions had undergone any change, or that human intercourse between the population groups was any way different during these two years, or that the most rigid quarantine precautions would have made the smallest difference in the mortality. The simple facts lead us to a different conclusion altogether, and this is that cholera comes and goes sometimes pressing lightly, sometimes heavily on the population in its passage, and we shall next see under what conditions it presented itself among the population groups which suffered.

13. In the preceding table it will be seen that cholera was most intense in Buldana district in 1884, and that out of 876 villages 10 yielded cholera deaths at a rate of 5·1 deaths per village. It was in the village of Bhalegaon in Mulkapur circle of this district that the first case of cholera in 1884 was reported. A mahar employed on the railway was seized, and died on the 3rd May in 12 hours of bowel complaint, but there is little doubt that the cause of death was cholera. "On the "next day a Hindu lad, who had no communication in any way with the mahar, was taken ill "in the same way, and died in 12 hours." There is said to have been no suppression of urine in "either case.

Two similar cases took place on 18th May, one of which died. On the 19th there were four cases, and one died. Up to the 28th May, when the Civil Surgeon visited the locality, there had been 11 cases, exclusive of the first two, and he continues:—"Whichever be taken as the first case the "disease was plainly indigenous. The disease was not anywhere in the district, and there had "decidedly been no communication with any infected place out of the district." The village consisted of 100 huts and a population of 508. The Medical Officer who visited the locality could detect no local cause for the outbreak. Excluding the first doubtful cases, there were 3 deaths out of 11 attacks. There was no more cholera in the district for three months, but on the 23rd September the disease appeared in the village of Makori, situated some 10 miles to the south of Bhalegaon. In this second locality there were 20 attacks and 6 deaths. The village consists of 275 huts, and the population numbered 1,300. There was no cholera in the district at the time, and no communication could be traced with any affected locality. The first case was in a child which in the forenoon partook of its usual food. At 4 p.m. it was seized with vomiting and purging. At about 11 p.m. it died.

This village differed considerably in its external sanitary appearance from the village first attacked. The locality is damp, the drainage defective; the house floors damp, and cattle were stalled within the village. The water was obtained from 35 wells, and appeared to be good. "The first case was "undoubtedly indigenous, and the disease was not confined to one spot in the village. Shortly after "the appearance of cholera in this village it broke out in five other villages in Malkapur circle, "none of them neighbouring villages to Makori." In all 12 towns and villages were attacked out of 201 in the affected circles. There were 149 attacks and 51 deaths.

14. Cholera next appeared at Ellichpur district on 4th September, 100 miles to the north-east of the places where it first appeared, and in which it still existed. "The first case was in a boy of 14, "who was seized with vomiting and purging in the morning, and died at night. Another fatal case "took place in a boy in the same hut on the same day. A third case occurred on the 9th September "without any communication with the others. It also proved fatal. In this district four villages "were affected, and there were 7 attacks and 6 deaths."

15. Akola district, where the disease appeared on 2nd November, is about 50 miles from Ellichpur, and the same distance in an opposite direction from Malkapur. Seven towns and villages in Akola yielded cases, of which there were 53, and 30 deaths. In the neighbouring Balapur circle there were 30 deaths. "The outbreak," says the Sanitary Commissioner, "was of indigenous origin."

The Balapur cases resulted from excessive feasting at a local festival, and the town itself "is in a "very insanitary state. . . . . There are no rules whatever in force, or arrangements for the "purposes of nature in the pet. The very drains in the main streets in the pet answer the purposes "of latrines. . . . . The drinking water is defiled. Men and animals pollute it. Khasarkera "is quite insanitary and noxious." The sanitary organization is in a most defective state. This Balapur experience included one of those cases which throw light on some points of cholera history. A traveller on his way to Akola halted a day at Balapur, where cholera was present. He was taken ill at Akola, about 10 miles away, and there died, but no other case followed. There was some condition present in Balapur which was not present in Akola. There were several examples of isolated cases in villages "occurring in seven different centres without starting an "epidemic of cholera in the district."

16. We have adduced these cases from the present Report to show the kind of information supplied to us by well observed first attacks. It is in this way alone that trustworthy information about epidemics can be attained, for after the disease has shown its presence by overwhelming numbers of cases there are elements of fallacy at work which it is almost impossible to eliminate, and hence any kind of epidemic theory may be adopted, however, false in fact it may be. There appears to be no doubt of the entirely independent character of these recorded seizures. The two factors, the epidemics and local and personal predisposing causes, were both present, but the former in a mild degree.

17. *Small-pox.*—This disease presents an epidemic character in these provinces not unlike that of cholera, as will be seen from the following annual death-rates since 1871 :—

Years.	Small-pox Death-rates per 1,000.	Years.	Small-pox Death-rates per 1,000.
1871	·2	1878	9·7
1872	3·8	1879	·03
1873	3·8	1880	·02
1874	·5	1881	·08
1875	·4	1882	·10
1876	·2	1883	1·50
1877	2·9	1884	·20

Of late years the mortality has much diminished, and the intervals between periods of epidemic increase have lengthened, but notwithstanding the diminished death-rate, small-pox mortality was still sevenfold the mortality from cholera in a non-epidemic year. Small-pox deaths were returned from all the districts, and from 62 out of 113 circles of registration, and nevertheless the disease was fatal in no more than 202 population groups out of 5,501. Out of 11 towns in the provinces 7 returned 43 small-pox deaths. The town which suffered most was Basim, which lost 32, or 2·7 per 1,000, from this disease.

18. The monthly prevalence of small-pox was as follows :—

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January	47	July	38
February	58	August	17
March	94	September	13
April	128	October	10
May	102	November	7
June	76	December	29

As usually happens the hot months yielded the most small-pox. Nearly the whole small-pox mortality of the year took place at young ages. Of the 615 deaths, 212 were under one year of age, and 384 between the ages of one and ten.

19. The birth-rate in 1884 was, as we have seen, 41·3 per 1,000 of population, the successful vaccinations were 30·3 per 1,000, and the small-pox death rate 0·2 per 1,000, while 596 deaths took place under 10 years of age out of a total mortality of 615, and the conclusion is obvious that vaccination must be advanced at the younger ages. Nevertheless the actual sum of operations has largely increased during recent times.

In the official year 1869–70 the ratio of successful vaccinations to population was only 3·2 per 1,000, since then it has rapidly risen and attained to 38 per 1,000 on two years, while in 1883–84 the rate had fallen somewhat to 30·3 per 1,000. The data show a large decrease of small-pox mortality and fewer epidemics since vaccination was introduced and extended, but the large death-rates at the younger ages show that it is not sufficient to have a high general vaccination rate unless it can be shown that the high rate is due to operations performed in the first year of age.

20. *Fevers.*—Deaths registered from fevers were those most generally distributed over the provinces in 1884. They were returned from all the six districts, from all the circles of registration, and from 4,012 villages out of 5,501. Fever deaths were likewise returned from all the towns. The registered fever deaths numbered 30,551, or 11·6 per 1,000 of the population, against a preceding five years' average of 15·1 per 1,000. There has been apparently a considerable reduction in the fever mortality in 1884 over the registered amount of the previous 16 years, which averaged 14·4 per 1,000. During the earlier years the registration appears to have been imperfect, but the rate for the last 10 years has been as follows :—

Years.	Ratio per 1,000.	Years.	Ratio per 1,000.
1875	11·9	1880	14·2
1876	18·2	1881	15·6
1877	15·6	1882	15·0
1878	38·9	1883	20·8
1879	14·8	1884	11·6

This abstract shows that fever in the Berars is liable to periods of considerable augmentation followed by decline in the death-rate.

21. The monthly deaths registered in 1884 were as follows:—

Months.	Fever Deaths.	Months.	Fever Deaths.
January	2,398	July	1,528
February	1,917	August	2,331
March	2,254	September	3,497
April	2,315	October	3,489
May	2,419	November	3,732
June	1,660	December	3,061

A diagram for each district gives the relation of rainfall to fever mortality, with the result that in all the districts the maximum fever death-rate follows the most of the rainfall. When the ground begins to dry the fever mortality rises.

22. A further analysis of the facts shows that the fever mortality varies considerably in different districts, as is shown by the following ratios:—

Districts.	Ratio per 1,000 for 16 Years' Average.	Ratio per 1,000 for 1884.
Amraoti	15·2	12·2
Ellichpur	15·5	11·0
Wun	16·8	15·8
Basim	10·0	6·9
Akola	16·2	12·9
Buldana	22·3	9·4
Total	14·4	11·6

These figures suggest some important points of inquiry. Why, for instance, should Wun return the persistently highest fever rate, and Basim the lowest? Are there any circumstances connected with the topography of districts to account for the facts, or in the habits and modes of life of the people, or in the condition of villages, or in their local position? The facts as they stand appear to show that some light at least may be obtained by following up such an inquiry. All that can be done with the case as it stands is to point out the probability of local drainage defects leading to local causes of malaria, as influencing the amount of fever.

23. The town fever death-rates slightly exceed those for the villages in the proportion of 11·9 for the former to 11·7 for the latter. The highest town fever-rate of the year was 19·8 per 1,000 from Mangrul, where a population of 6,122 lost 121 by fevers, showing the presence there of serious local fever causes.

24. *Bowel Complaints.*—Deaths under this head were 9,319, or 3·5 per 1,000 of the population. The mean death-rate for 16 years had been 6·2 per 1,000. But the annual rates had varied greatly. The lowest rates, 2·9 per 1,000, were registered in 1868 and 1869, and the highest, 12·6 per 1,000, in 1878, which was the famine year. The rates registered in different districts show the same diversities as the rates from fevers; but it will be sufficient to state that the lowest rates have been those from Wun district, which on a 16 years' mean have been 1·8 per 1,000, and only 1 per 1,000 in 1884, while the highest rates have been returned from Akola. These averaged 9 per 1,000 for 16 years, and the rate for 1884 was 5·2 per 1,000. The rate for 1884, when compared with the previous five years' average, was as 3·5 to 4·6 per 1,000. The monthly deaths registered were as follow, and they show a large increase in the latter months of 1884, corresponding in this respect with the monthly mortality from fevers:—

Month.	Bowel Complaint Deaths.	Months.	Bowel Complaint Deaths.
January	958	July	809
February	628	August	975
March	538	September	1,431
April	540	October	1,171
May	535	November	918
June	375	December	741

It would appear as if these diseases, like fever, were influenced by climatic causes. The highest town rate from bowel complaints was 5 per 1,000 in Malkapur town, situated in a cholera district. These diseases were generally diffused over the provinces, as is shown by the fact that 108 out of 113 circles returned deaths, and 1,945 villages, out of 5,501, suffered.

25. We shall conclude this sketch of the epidemic history of 1884 by abstracting the following table, showing the relation month by month, of the different epidemic death-rates to the chief climatic elements. Small-pox is augmented by high temperature as it is elsewhere in India.

Cholera was mainly an endemic disease. The months of greatest fatality from fevers and bowel complaints were the cholera months, when the humidity, rainfall, and temperature here higher. If we admit that these elements exercised a certain influence on the general health of districts, we may safely admit also that they acted injuriously on loca disease causes by increasing their activity.

Months.	Mean Maximum Temperature.	Mean Range.	Mean Humidity.	Total Rainfall.	Total Deaths, 1884. Cholera.	Small-pox.	Fevers.	Bowel Complaints.
	°	°		Inches.				
January	79·1	26·9	40	·45	—	47	2,398	958
February	86·9	28·7	33	·09	—	58	1,917	628
March	97·1	29·3	29	·39	—	94	2,256	526
April	102·5	28·1	29	·35	—	128	2,315	540
May	105·5	26·7	26	·01	5	102	2,419	535
June	97·4	21·0	50	4·47	11	76	1,660	375
July	84·3	12·0	79	12·26	—	28	1,523	509
August	85·9	13·4	73	5·91	—	17	2,331	975
September	83·3	12·9	79	14·17	14	13	3,497	1,481
October	85·4	20·3	56	2·46	25	16	3,489	1,171
November	82·3	26·3	41	··	48	7	3,782	918
December	76·7	22·9	54	5·76	—	29	3,016	741

26. *Injuries.*—Under this head were returned 177 suicides, 57 deaths from wounding, 537 from accidents, and 188 from snake-bite and wild beasts, making in all 959 violent deaths against a 16 years' average of 963.

27. All other causes yielded 23,277 deaths, or 3·5 per 1,000 of the population. But an attempt was made to classify 3,261 deaths in 120 villages, with the following results, which it is important to give, premising, however, that the village nomenclature is only approximately correct.

Diseases.	Deaths.	Diseases.	Deaths.
Zymotic Diseases.		*Local Diseases.*	
Small-pox	18	Epilepsy	1
Fevers	1,515	Sunstroke	1
Measles	4	Headache	2
Puerperal disease and childbirth.	57	Respiratory affections	489
		Jaundice	56
		Colic	43
		Hiccough	3
		Dysentery and diarrhœa	528
		Worms	20
Constitutional Diseases.		Spleen disease	1
		Piles	1
Rheumatism	39	Stone in bladder	2
Syphilis	21	Gonorrhœa	3
Scrofula	4	Abscess	4
Phthisis	8	Atrophy and debility	225
Dropsy	24	Old age	73
Leprosy	23	Injuries	44
Scurvy	7	Other causes	15

On these data the Sanitary Commissioner makes the following remarks:—Respiratory affections include pneumonia, bronchitis, and asthma. Of 225 deaths from atrophy and debility, 200 were amongst children between one and three years of age, due probably to teething, want of nourishment, &c. Deaths from puerperal fever and childbirth are considerable, "as might be expected in a "country where poor women have no skilled assistance at this critical time." Imperfect as are the data, they throw much light on death causes, and consequently on the health improvements necessary. They appear to show that, in the absence of cholera, one half of the deaths arose from zymotic diseases. That about a seventh part was due to chest diseases, a sixth part to bowel diseases, and a very large proportion to diseases incidental to weakened stamina, the result of fevers due to malaria and to the prevailing local disease causes in villages. On the whole, then, we are indebted to the Sanitary Commissioner for increasing our information on these village diseases, and we cannot do otherwise than express a hope that similar inquiries may be pursued in other Governments to prepare the way for a more efficient system of registration of death causes than has hitherto been practicable in India.

28. As regards the remarks of the Sanitary Commissioner about puerperal deaths due to want of skilled assistance in childbirth, it may not be out of place to state the present position of this question in England, where there has been no such want of skilled aid in times past, and where, nevertheless, the childbed death-rate has undergone a very remarkable reduction in recent years.

About 15 years ago the statistics of 16,774 deliveries in home practice were given by Dr. McClintock and Dr. Matthews Duncan, showing a mortality of 131 on nearly 8 per 1,000, or one death for every 125 deliveries. The fact shows that something else was at fault, and not the skill of the attendants. The Registrar-General had thrown a little light on the subject by showing that the maternal death-rate in towns was higher than in country districts, while the general death-rate was equivalent to one death in 200 deliveries. The whole question, together with the probable causes of mortality, had

attracted attention in different foreign countries as well as in England, and it was dealt with in Miss Nightingale's notes on lying-in hospitals published in 1871. Of late years a noteable reduction in the death-rate has taken place, for according to the Registrar-General's report the maternal death-rate in 1883 in England and Wales was equivalent to one death in 230 births. Again, in the Rotunda Hospital, Dublin, in the seven years ending in 1864, the deaths were one in 32 deliveries, while in the Report for 1885 the proportion was one maternal death in 126 cases.

The skill has remained the same, but it is clear that the conditions of labour have been materially improved, and that the influence of sanitary surroundings is becoming more and more recognized in childbirth and in maternity hospitals as it has been in general hospitals.

We have not the means of knowing accurately the death-rates of lying-in women in these Indian villages, but we can approach to it by calculating backwards through the death-rates given in the preceding tabular statement, with the result that the not improbable death-rate of lying-in women is somewhat about one death for every 100 deliveries. Now we know something of the sanitary state of the villages where such results are arrived at, and it would be in perfect accord with all past knowledge and experience to include a lower childbirth death-rate among the savings of life to be aimed at and anticipated by village sanitary improvements.

29. *Sanitary works (Civil).*—Berar contains seven municipalities, and the present Report gives brief but sufficient abstracts of the sanitary measures carried out in them in 1884, and there are a few points of practical interest in the year's proceedings which may be noticed for the sake of information.

30. And first as regards the death-rates, which stood as follows in comparison with the previous five years' averages:—

Municipalities.	Population, 1881.	Death-rates per 1,000.	
		1884.	Previous Five Years' Average.
Amraoti	23,538	25·4	24·6
Akola	16,614	17·6	33·5
Khamgaon	12,390	22·5	29·7
Shegaon	12,079	29·7	33·3
Akot	16,187	28·9	33·3
Ellichpur	26,226	24·8	36·5
Basim	11,576	20·2	28·4

These mortality statistics show considerable improvement in the public health, but the registration is obviously defective, and for two towns, Khamgaon and Shegaon, the five years' rates are estimates. Besides this, 1884 was a non-epidemic year, so that the figures are matters of record more than of actual fact.

The aggregate population of these seven municipalities was 118,074, and their outlay under each head of sanitary improvement was as follows in 1884:—

	Rs.
Conservancy	33,171
Drainage	7,318
Water-supply	15,995
Total	Rs. 56,484

For these purposes the year's expenditure was about a shilling a head, or about a third of the income.

The public health work done was as follows:—

31. *Amraoti.*—Surface drainage extended in the eastern part of the town, but the western part still undrained. The new water-supply was still incomplete. The source is a lake five miles from the town, and water will be laid on by pipes. Conservancy cost Rs. 10,323, or a little over 10d. per head. Bathing water is collected and carried away. The "nightsoil is carted to about a mile outside the "town, and buried in trenches. The site of these trenches has been cropped this year by the "municipality with wheat, peas, and linseed. The experiment is stated to have been a decided "success."

32. *Akola.*—"Altogether some 8,750 running feet of masonary surface drains have been completed, "and the house moris or cesspools, where they abut on the drains, open into them." A scheme for completing the drainage was being prepared. The water-supply is still in an unsatisfactory state, although much has been done by the municipality to improve it. It is proposed to construct a tank about three miles from the town, and to lay on the water by pipes. In this town the sweepings are collected by the conservancy and deposited in dustbins, whence they are sold to a contractor, an arrangement which works well, and "brings in a good round sum to the Committee every year." The house sewage is allowed to sink into the subsoil, or it is carted away by the conservancy, which is "very costly." There is no escape from the outlay, however, until the town is properly drained. The suggestion made in the report, to complete the drainage by a loan, and to connect the houses with the drains, is the only alternative, but it must be remembered that drains, whether opened or closed, require a sufficiency of water to remove the sewage to the outlet.

33. *Khamgaon.*—This small town of 12,390 inhabitants has been surface drained, and the house cesspits have been connected with them, and cesspits can now be abolished. The new water-supply, which will yield a daily supply of 20 gallons per head of the population, was nearly completed from a tank. "Pipes have been laid down in most of the streets," and masonry cisterns, hydrants, and cattle troughs were being provided. We may restate here that, to prevent nuisance and to secure the healthy action of the drainage system which has been adopted, a water-supply for washing out the surface drains continuously is a matter of necessity. In this town the nightsoil is trenched, and a very satisfactory result in the growth of tobacco and pumpkins was obtained on the site. The result has been that other people have applied to have the manure, and, if the example is followed, the great difficulty in cleansing will have been met.

34. *Shegaon.*—This town of 11,079 inhabitants is considered to be so poor, rightly or wrongly, that it cannot complete the water-supply, although a tank was provided by subscription and the water brought to the outskirts, where it still is. The town wells are all brackish. The outlay for conservancy was just a penny per head, or Rs. 779 for the whole population for the year. Nearly 6 per cent. of the inhabitants died in 1883, and nearly double this rate in 1878.

35. *Akola.*—This town has "a deep closed drain running under the principal streets, and open "surface drains discharging at points into it." This system will be extended to the whole town as funds are available. The water-supply is from wells, and is said to be good and abundant, but the sanitary condition of the supply can only be known by analysis. The drainage arrangement and water-supply are both defective. At present the house sewage is run into the street drains, or into masonry receptacles periodically emptied, "the contents being scattered over the streets." In cases such as this, the remedy required is to have a consistent scheme prepared, including the drainage and water-supply, which ought always to go together, and such haphazard execution of works, to be put aside and resumed when funds are available, is a measure always to be deprecated. It is not in this way that sanitary improvement can be accomplished.

36. *Akot* has a population of 16,137, and it expended in 1884 a sum of 602 rupees for cleansing, or less than a penny per head.

37. *Basim.*—This town of 11,576 inhabitants is drained by side cuttings in the streets. "The "deficient drainage of the civil station, which yearly gives rise to so much sickness amongst the "members of the police force, owing to dampness of their barracks, has not yet been remedied." This was reported on in 1879. The Sanitary Commissioner points out the two alternatives, either to drain the station or to remove it to a better locality. The water-supply is the same as formerly, from wells and tanks. House sewage is removed by the municipality, and the town garbage is burnt in cinerators. In this town private latrines are cleansed by the municipality, which is an important improvement, and Basim is remarkable for the amount spent on conservancy, which was Rs. 2,770, or about 6*d.* a head, when compared with the outlay in other towns, and it had the lowest death-rate, 20·2 per 1,000, in 1884.

38. *Ellichpur.*—This, which is the most populous town in the Berars, with a population of 26,728, is in a backward sanitary condition. Its surface drainage was only begun, and 97*l.* has been expended on it. Part of the town only is supplied with water from a distance by pipes, the remainder from wells and the river. Its conservancy arrangements are defective, and cost about 5*d.* per head. Its five years' average death-rate had been 36·5 per 1,000, and in 1884, without a single death from small-pox or cholera, its rate was 24·8 per 1,000, one-third of which arose from fevers.

39. The impression produced on the mind of the Sanitary Commissioner by the facts in these towns is that "steady progress is being made in works of sanitary improvement." We are not disposed to call this opinion in question, but the facts regarding the sanitary condition of the municipal towns stated in the report clearly show that a far more rapid advance is required to shield their inhabitants from those fatal epidemic outbreaks which may occur at any time under the existing sanitary conditions.

40. *District Sanitary Improvements.*—The total expenditure under this head was as follows:—

	Rs.
Civil stations	24,173
Non-municipal towns	33,053
Villages	38,691
	95,917

This amount includes the construction and up-keep of roads, serais, &c., but the sanitary expenditure was 67·5 per cent. of the sum, 31·1 per cent having been allotted for conservancy, 17·9 for drainage, and 18·5 per cent. for water-supply. Besides the outlay for current sanitary work, several important permanent improvements were carried out in the East Berar division by the Public Works Department. These included four water-supply tanks and seven anicuts. In the West Berar division a number of tanks were constructed and repaired, and surveys made. All these works ought to have an important influence on the sanitary state of districts.

41. *Jails.*—The jail construction is for 1,345 prisoners. The average daily strength in 1884 was 1,030·89. The largest number on any one day was 1,292. The average daily sick was about 1¼, and there were 9 deaths. The two jails of Amraoti and Akola, which had the largest numbers at one

tions in prison, but in each case considerably under the construction, yielded the largest percentage of daily sick, and the nine deaths took place out of 444 prisoners in Akola jail. The death-rate in this jail on its average population was 20·2, and on the whole jail population of the province it was 8·7 per 1,000. The causes of death are not stated, but with an annual admission rate of 486 per 1,000, a daily sick-rate of 10 per 1,000, and a death-rate of 8·7 per 1,000, the year's results, when compared with those in other jail districts, are favourable.

32. *Village sanitation.*—The best way to obtain an idea of the present state of this all-important work will be simply to transcribe what the Sanitary Commissioner says about it. This is as follows:—"Since the introduction of the Residents' Book Circular XVI. of 1880, laying down a code of rules "for village sanitation, considerable improvement has undoubtedly been effected, and where these "rules are observed the village site is clean and the surroundings undefiled. In many villages, how-"ever, these rules are still a dead letter. The patel knows not of their existence, or if he does, will "say they are with the patwari, with whom the circular has been so carefully preserved as to be "forgotten. What is required is that when any inspecting officer visits a village he should first call "upon the patel to produce the rules, and then ascertain if they are given effect to, or any attempt "made to carry them out, and upon tahsildars specially their duties in this respect should be strongly "impressed." This merely means that new rules, or rules new to the people, have no self-operative qualities in India, any more than they have anywhere else, and that while rules supply the instrument, the executive supplies the handle, and the two portions must always be joined together. Any way the Sanitary Commissioner has stated the principle which must be applied in practice, and skilled efficient inspection would otherwise be a means of enlightening the people, for we are told that their minds "are gradually becoming familiarized with the fact that what is required under these rules is "for their own benefit." For the same object the Government of India directed the preparation of a school book by their late Sanitary Commissioner for use in all schools, but from some misunderstanding its use in the Berars has been limited to the training colleges. We concur in the view of the Sanitary Commissioner that this primer "should constitute one of the regular class books taught "in every school, not merely in the higher classes but in the lower ones also." It was, indeed, for this purpose it was prepared.

There is an Appendix to this Report, giving detailed notes of town and village inspections by the Sanitary Commissioner, but as their general result has been already stated it is unnecessary to enter into the details at present.

In conclusion. The report for 1884 shows very good inspecting and reporting work on the part of the Sanitary Commissioner. It cannot, however, be said that it adds much to our previous knowledge of the sanitary history of the comparatively small population of these provinces. Much addition in this direction was not to be expected, but we now know for a certainty that the Berars are subject to sudden and violent outbreaks of fatal epidemics, and that no amount of inspecting and reporting can diminish this liability. In the present state of public health all that the Sanitary Commissioner can do is to repeat incessantly this fact, but to turn it to practical use for the purpose of saving life or working power to the people is beyond his power. This belongs to the executive, and it is in extended and more active work that any real good can be expected. The difficulty in the Berars, as in other parts of India, is twofold, first, deficiency of funds, but secondly, the far greater deficiency of real energy in dealing with sanitary measures in themselves of a very simple kind, and which no increase of funds could altogether overcome. All we can do is to call pointed attention to what appears to us to be the practical outcome of this Report, but it rests with the Government to take such steps as may be necessary to secure the exercise of the requisite power, whether in municipalities or villages, for removing the disease causes to which the Sanitary Commissioner has called attention year after year.

We have no intention in these remarks of implying that no good work has been done, but to a certainty the present health history of these provinces would have been different if the executive had followed more closely the leading of the sanitary history.

27th March 1886.

No. 9.

Memorandum of the Army Sanitary Commission on the Report of the Sanitary Commissioner for Assam for 1884.

1. The population adopted in this Report is that of 1881, which was 4,527,934. The registered births in 1884 were 120,483, or 26·61 per 1,000. The area of registration is not materially different from the area of 1883, and as no allowance apparently can be made for increase of population, the ratios calculated on the census of 1881 are probably too high.

2. The birth ratios vary in different districts. Leaving aside the rate of 48·38 per 1,000 returned from the 744 inhabitants of Tura, the highest rate, 41·65 per 1,000, was registered in Goalpara district. The other districts returned rates at and above 24 per 1,000, with the exception of Lakhimpur, which was 19·38 per 1,000. Birth registration is improving in all the districts, and showed a general increase in 1884 of 2·76 per 1,000 over the ratio of the preceding year. For every 100 females 109 males were born.

3. The deaths registered in 1884 numbered 132,992, or 29·37 per 1,000, hence, if the registration were correct, the deaths in 1884 would have exceeded the births by 12,509, or 2·76 per 1,000 of the

population. It would hence appear that the registration of deaths is better done than that of births, and not that the population of the province has diminished. For every 100 female deaths registered there were 113 deaths of males. The highest death-rate was returned from Goalpara, namely, 49·50 per 1,000. The birth-rate in this district was 41·65 per 1,000. Both ratios would apparently show good registration work, but large numbers are no real test of accuracy, for, if they were so, this district would show a loss of 7·85 per 1,000 of its population, which is not likely. All that can be said about the registration is that the actual numbers registered are increasing.

4. The tea garden registration has been placed in a better position by the use of a correct basis of the mean resident population, which, excluding the small numbers in the Goalpara gardens, amounted in 1884 to 260,758. The births among this number were 8,256, and the deaths 10,668, giving a birth-rate of 31·66 and a death-rate of 40·91 per 1,000 of the average population. Of course allowance would have to be made for the element of age, but still the birth-rate would supply its quota of infantile mortality to the general rate, which among people engaged in country work is on any supposition very high, and affords ample scope for the sanitary improver in reducing it. But when the district tea garden rates are taken separately, we find that some of them are excessive, and require special examination and report. They are as follow:—

Districts.	Population of Gardens.	Deaths, 1884.	Deaths per 1,000.
Kamrup	2,541	204	80·28
Darrang	23,458	1,094	46·72
Nowgong	11,318	704	62·20
Sibsagar	62,993	3,068	48·70
Lakhimpur	45,066	1,198	26·58
Sylhet	36,114	1,690	46·79
Cachar	79,268	2,710	34·18
Total	260,758	10,668	40·91

We take it for granted that, as the deaths are placed in column alongside the births, they refer to the whole population, including children under the working ages, and, if this be so, it would introduce an error into the ratios by charging the infantile mortality against the tea gardens and their management, and, to avoid such a mistake, we would suggest whether the actual deaths at the working ages and the actual working population should not be used in striking the death-rates in future, and given as well as the present data, which as they stand can only be described as lamentable.

5. The average death-rate in 10 Sadr towns was 29·87 per 1,000 on a population of 60,091, and the rate on 40,459 inhabitants of 12 sub-divisional towns was 35·39 per 1,000. The Sadr towns present some extraordinary registration results. Shillong, for example, returns the births of 84 males for ever 100 females, and the deaths of 350 males to 100 females. This is the worst case, but the others present similar instances. They are perfectly well known, and are accounted for on the spot by the present state of the machinery, but with all the errors there is evidence that in the midst of great difficulties the work is advancing, and we must hope for the best.

6. *Causes of death.*—The following were the registered death causes in 1884:—

Causes.	Total Deaths.	Deaths per 1,000.
Cholera	22,276	4·92
Small-pox	4,781	1·06
Fevers	66,527	14·69
Bowel complaints	16,157	3·57
Injuries	1,180	0·26
Other causes	22,071	4·87
All causes	132,992	29·37

The difference between the general death-rate of 29·37 per 1,000 in this table and the previous five years' average rate of 18·68 per 1,000 is solely due to the extended area of registration and improved record.

Under such conditions it is not possible to give a trustworthy account of the past disease history, and we must take the figures given in the Report as the best attainable at present.

7. *Cholera.*—The following registered deaths from this epidemic have been returned for the last four years:—

	Deaths.
1881	5,010
1882	21,055
1883	14,908
1884	22,276

The largest cholera mortality in this group of years was in 1884. It amounted to 4·92 per 1,000, against a previous five years' average of 2·73 per 1,000. This, however, does not include a few deaths in the Khasi and Jaintia hills and Tura, which have only recently made returns.

8. In the year under review all the nine districts returned cholera deaths 21,824 in number, or 4·93 per 1,000, and of the 22 towns three only escaped the epidemic. The others returned 452 deaths, or 4·49 per 1,000. The highest death-rates of the year were returned from the towns of Mangaldai and Nowgong, and these were 17·34 and 16·95 per 1,000 respectively. Nowgong district returned the highest district rate of the year, namely, 8·85 per 1,000. Cholera was generally distributed over the province. Deaths from it were returned from 415 circles of registration out of 661. There are 16,205 villages, but all those returning deaths are not given. The number which made returns was 3,551, or above 23 per cent. of the villages in the same districts. The deaths returned by villages would average four deaths per village.

9. The monthly incidence of cholera was as follows for the whole province, but, as we shall see, its incidence varied considerably in the two great valleys:—

Months.	Cholera Deaths.	Months.	Cholera Deaths.
January	204	July	2,423
February	258	August	1,069
March	1,052	September	934
April	1,979	October	1,442
May	4,254	November	2,811
June	3,866	December	1,984

As these figures stand, they appear to be a record of two consecutive epidemics, but the real facts are shown in this abstract:—

Months.	Registered Deaths from Cholera.			
	Brahmaputra Valley.	Surma Valley.	Hill Districts.	Total Deaths.
January	131	71	2	204
February	55	202	1	258
March	629	417	6	1,052
April	1,370	603	6	1,979
May	2,593	1,645	16	4,254
June	2,942	910	14	3,866
July	2,196	188	39	2,423
August	880	169	70	1,069
September	676	222	31	934
October	675	706	61	1,442
November	798	2,006	12	2,811
December	222	1,761	1	1,984

These data are only for a single year, yet they show that in 1884 the epidemic history was by no means the same in the two valleys. From figures in the Report it is obvious that while the epidemic history of the Brahmaputra valley was essentially the same in 1883 as it was in 1884, the Surma valley epidemic in the latter year approached more nearly to the monthly course of the Brahmaputra cholera than it did in 1883.

10. This subject is of considerable importance in the topographical and climatic history of cholera, and as a further contribution to its elucidation we shall place side by side the cholera deaths and rainfall in Nowgong and Sylhet, the former in the Brahmaputra, the latter in the Surma valley:—

Months, 1884.	Nowgong.		Sylhet.	
	Cholera Deaths.	Rainfall.	Cholera Deaths.	Rainfall.
January	—	0·07	58	0·07
February	2	1·14	114	2·52
March	12	2·87	366	10·32
April	32	4·52	485	15·56
May	62	6·19	979	25·45
June	348	9·74	544	12·41
July	651	17·80	136	13·35
August	225	13·07	94	41·25
September	263	5·66	208	7·01
October	304	3·12	694	12·01
November	536	0·12	1,947	0·94
December	148	—	1,685	—
Total	2,782	63·60	7,197	114·11
Ratio per 1,000	8·96	—	3·65	—

This abstract shows the influence of rainfall on cholera in two typical cases, both as regards its amount and distribution.

In Nowgong, with less than half the rainfall in Sylhet, the cholera death-rate is much more than double. In Nowgong the death-rate rises with decrease of rain. In Sylhet, at the time the rainfall is so great as to flood the country, cholera mortality undergoes a marked diminution, but it again increases when the flood waters have passed away and the earth surface has re-appeared. "All the "circumstances which are said to promote the spread of cholera and aggravate its intensity exist in "Sylhet everywhere,—high temperature, a moist stagnant atmosphere half the year round, lowness "of position, unwholesome food, bad water, and defective sanitary arrangements generally." This is Dr. Macnamara's account, and the Sanitary Commissioner adds to it, "crowded population on "many areas." Nevertheless, in the presence of these local causes, climatic conditions, together with local topography, appear to exert a palpable influence on cholera in the Surma valley. Anyway, the rainfall cannot be interfered with, but we can deal with the local causes which unfortunately we cannot compare with those of Nowgong district, in which the maximum mortality of the year took place, because the local reports give no account of them, at least specifically, but they leave no doubt of their existence, much as they have been hitherto, and we may safely accept the following view of the Sanitary Commissioner as showing generally what are the common predisposing causes of cholera in Assam:—"The statistics of cholera in the province during the year are illustrative solely "of the fact that the disease is persistently endemic, with periodical epidemic outbreaks of great "severity. As yet no progress has been made towards reducing this annual grievous mortality "by the introduction of large sanitary measures. In Shillong alone has a pure and undefiled "water-supply come into the daily use and habits of the people, but this is no test, as cholera has "only once (1879) been epidemic in this station. Elsewhere in Assam sanitation in degree "commensurate with the occasion has no place, and the rise and fall of cholera is wholly dependent "on natural laws which are not yet fully understood. The only consistent observations are that the "flood of waters spreading over the Surma valley is associated with a temporary disappearance of "the disease, and that February is almost always the month in which cholera is at a minimum "everywhere. Until sanitary measures are supported by a much greater local expenditure" (and we would add with far more energy and perseverance than appears to have been spent on them, a matter of more importance than money), "the annual statistics are simply a reflection of unchecked "waste of life."

11. *Cholera in the tea gardens.*—We have already seen that the cholera death-date for the whole of Assam was 4·92 per 1,000. In the tea gardens there were 2,161 deaths from the epidemic, or 8·3 per 1,000 of the tea garden population, not far short of double the rate for the province. The mortality was distributed as follows:—

Districts.	Cholera Deaths per 1,000 of Population.	
	General Population.	Tea Garden Population.
Kamrup	5·62	29·4
Darrang	6·46	11·8
Nowgong	3·95	14·3
Sibsagar	5·24	10·0
Lakhimpur	2·55	4·3
Sylhet	3·69	7·5
Cachar	5·89	7·6
Total	4·92	8·3

The tea garden registration is no doubt more accurate than that of the districts, and hence the comparison presented by the figures is not absolute. But this objection does not apply to the tea garden mortality, which presents a record of very high cholera death-rates, among a body of people under control and having medical officers on the spot. It is necessary to ask why it is that so many lives are annually sacrificed from cholera in these establishments. We have suggested this inquiry in former memoranda, but the mortality only is reported in 1884 without any corresponding account of the local causes of this great sacrifice of life, or what is being done to prevent it in future. We have, however, the views of the planters on the subject, as follows:—"Dr. Campbell connotes the "general opinion of the tea planters that cholera is introduced in their gardens by newly imported "batches of coolies, while at the same time it is admitted that the coolies are landed from the "steamers in good health, that cholera is prevalent generally in the district, and that some time "elapses before the coolies are themselves affected." The facts appear to show that there are causes of some kind in the tea gardens themselves which predispose the coolies to attacks of cholera during epidemic seasons, and we would suggest that rigid inquiry should be made into the conservancy arrangements, water-supply, and drainage of the localities where the workpeople live. Something must be at fault. The Sanitary Commissioner adduces this case, and also another instance of hypothetical causation from the passage of a train of coolies during the Aka expedition, whose habits no doubt were far from cleanly, but he adds that "their habits could not be worse than the resident "population, or the labourers on tea gardens," a remark which throws light on the cholera among tea garden coolies, and shows where the remedial local evils should be sought for and dealt with by

the tea garden authorities. As the Sanitary Commissioner very properly remarks on these alleged importation occurrences, they show "how readily blame is thrown on exceptional occurrences, while "every detail commonly supposed to favour cholera outbreaks is present ordinarily in the vital "conditions of the complainants."

It is from such attempts to shirk responsibility, as we have often pointed out, that danger to real sanitary work arises in India as everywhere else, and which for many years have led people to throw the blame of cholera on the legitimate pursuits of commerce instead of on their own foul seaports, and their general neglect of sanitary work.

12. *Small-pox.*—There were 4,781 small-pox deaths in Assam districts in 1884, against 6,162 in the preceding year, and 3,129 in 1882. The death-rate in 1884 was 1·05 per 1,000, while the previous five years mean was ·72 per 1,000. Small-pox deaths were registered in all the districts in 202 registration circles, and in 1,483 villages, but the returns for three districts do not give the number of attacked villages. Ten towns out of 22 returned small-pox deaths. The district death-rate was 1·02, and the town rate was 2·39 per 1,000. It seems probable that part of this difference may be due to better town registration.

13. The monthly prevalence of small-pox is shown by the following abstract of deaths :—

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January	436	July	336
February	583	August	248
March	796	September	118
April	788	October	69
May	800	November	68
June	545	December	94

Out of 4,781 small-pox deaths 990 were under one year of age, and 2,375 between 1 and 12 years of age. As the numbers vaccinated at the same ages are not stated, we have no means of connecting the facts, but the very large proportion of deaths under 12 years of age shows the need of extended vaccination among children. There were 253 small-pox deaths in the tea-gardens, somewhat under 1 per 1,000 of the population, but of these deaths 146 took place in Cachar district, where the disease yielded the highest rate of the year, which was 2·37 per 1,000, while the tea garden rate exceeded 1·8 per 1,000, showing that the more severe character of the disease in Cachar influenced the death-rate in the tea gardens.

14. *Fevers.*—Besides the statistics there is little additional information under the head of fevers in the present report. The actual mortality, so far as this has been registered during the last three years, has been the following :—

Years.	Total Fever Deaths.	Ratio per 1,000 of Population.
1882	60,622	13·38
1883	67,494	14·90
1884	66,527	14·69

The mean fever death-rate for the preceding five years was 10·15, but this affords no proof that fever mortality has been on the increase. It only shows that more deaths were registered.

15. Fever deaths were registered in all the districts, and the numbers registered differed very greatly in them. Leaving out the less populous areas, we find that the fever-rates as registered were between 8·81 per 1,000 in Lakhimpur and 38·03 per 1,000 in Goalpara. In such a climate as exists in Assam, these figures only show the state of the registration, and not the fever prevalence. Deaths were returned from 540 circles of registration out of 661, and a large proportion of the villages (10,667 out of 16,205) suffered. But even these last figures show that many deaths registered under the fever heading in some districts must have escaped registration in others. This result is, moreover, rendered more probable by the fact that all the circles in Goalpara, Darrang, and Sylhet returned fever deaths.

16. The registered monthly fever deaths were as follows :—

Months.	Fever Deaths.	Months.	Fever Deaths.
January	4,838	July	6,121
February	4,260	August	5,629
March	4,162	September	5,535
April	4,540	October	5,935
May	6,275	November	6,285
June	6,952	December	5,920

All the 22 towns returned fever deaths, and their rate was 10·93 per 1,000.

17. The best way to obtain information on the relative prevalence of fever and rainfall will be to take two districts, Goalpara in the Brahmaputra valley, and Sylhet in Surma, rather than to add together all the district falls and the fever deaths. This comparison stands as follows:—

Months.	Goalpara.		Sylhet.	
	Fever Deaths.	Rain.	Fever Deaths.	Rain.
		Inches.		Inches.
January	1,338	0·24	1,697	0·07
February	1,283	0·34	1,334	2·52
March	1,159	5·47	1,379	10·02
April	1,318	7·86	1,507	14·05
May	1,676	14·62	2,099	25·46
June	2,009	15·15	2,358	17·41
July	1,687	6·95	1,842	13·35
August	1,268	3·74	1,875	6·25
September	1,151	3·39	1,635	7·61
October	1,288	2·28	2,192	12·03
November	1,399	—	2,593	0·94
December	1,405	—	2,222	—
Total	16,976	65·25	22,933	144·11

The Goalpara rainfall is that of Dhubri, the head quarter town, and that for Sylhet is of Sylhet town.

The general result is that in Goalpara district, with a total annual rainfall of 65·25 inches, the fever death-rate averaged 35·03 per 1,000, while in Sylhet, with a rainfall of 144·11 inches, the fever death-rate was 11·64 per 1,000, affording a clear indication that the amount of fever depends on other factors than the amount of rain. In Goalpara the monthly fever-rate attained its maximum together with its maximum rainfall. But in this case the fever deaths in the months following were more numerous than in the months preceding the maximum rain. In Sylhet there was also rise in the fever-rate after the decline of rain.

The practical conclusion in either case would be that Assam is very decidedly a malaria generating country, while, so far as local information can be obtained, the disadvantages of sites are not lessened, but increased, by other local causes which in all probability bear a very important relation to the prevalence of these fevers.

On the other hand, the Sanitary Commissioner states that "the body of registrars name fever as a "cause of death simply because there had been a symptomatic increased temperature sensible to an "ignorant observer." We cannot, therefore, rely on the nomenclature for guidance in sanitary work. As the case stands, the Report estimates that perhaps one third of the so-called fever deaths "are climatic or malarial, and due to natural causes, under which the people must live and die for "generations to come; a third are probably due to the habits of the people, their insufficient "clothing and bedding, their exposure, their food, and privations, and the remaining one-third would, "under a more perfect system of registration, be entered under other classes of disease."

18. To the malarial group must finally be assigned the *Kala Azar*, which local inquiry has discovered to be only a local name for malarial fever and its consequences. The darkening of the skin, from which it take its name, is an exceptional character, and its fatality is partly due to the difficulty of bringing the scattered cases under treatment, and partly due to the unfounded idea of its contagious character, which leads to neglect or even to exposure of the sick. Government is doing what it can to provide medicine and attendance, but the following statement by the Sanitary Commissioner shows what the obstacles are, while it points out the difficulties in the way of sanitary work generally. He says, "Villages where great mortality had been reported could not be reached; "there are no roads, the jungle and forest tracts are wide and dense, with marshes, rivers, river "ponds, and ditches all over the place, and even the police find it impossible to keep communica-"tions open for several weeks at a time." And again, "The village sites were badly placed for "drainage, the homesteads and dwelling-places were most insanitary, the water-supply of each "homestead was truly abominable, the food stuffs defective both in staple, nourishment, and variety, "and the clothing insufficient." No doubt the difficulties in the way of improvement are great, but so far as the facts lead us, they appear scarcely to warrant the despondjng conclusions which follow. He adds, "To provide wholesome water for each village, to drain the district, to change all the "village sites, to clear the jungle about and burn it, are impossible measures." Of course, under any Government charged with the sanitary care of a country such as this is, if these simple things cannot be done, it becomes a clear duty to remove the people, and in Goalpara at least the Report appears to consider the land tenure as the final cause of the whole evil. With this consideration we have nothing to do, more especially as it is clear that the whole question of these fevers is part of the epidemic question of India, and as such it is simply a question of village organization and improvement. The people, no doubt, are in a low state of civilization, lower perhaps than they are in other provinces, but still it is far from certain that they cannot be guided in looking after their own interests in these matters. At all events, it would be better to try what can be done in a single thana than to throw up the whole case as hopeless.

19. *Fever in tea gardens.*—The fever-rate in these gardens was 6·4 per 1,000. A low rate if the nomenclature were the same as that in use among the civil population. This, however, is not likely to be so, as the garden Medical Officers diagnose the cases.

20. *Bowel complaints* were returned as death causes in 16,157 cases, or 3·56 per 1,000 of the population against a previous five years' average of 2·35 per 1,000. The Sanitary Commissioner considers the reporting imperfect, which we must hope to be the truth of the matter for the sake of the tea garden administration, for the year's statistics give a death-rate among the coolies from bowel complaints of 10 per 1,000.

21. From *Injuries* there were 1,180 deaths recorded, or ·26 per 1,000 of the population. Under this head were included 68 suicides, 808 deaths from wounds and accidents, and 304 from wild beasts and snake-bite.

22. *All other causes.*—There were 22,071 deaths, equal to 4·87 per 1,000 registered under this head. No details had been received to indicate the causes of death in these cases, but it may be of interest to give the following general statement on the subject:—"Goitre is endemic in the Newgong "district. . . . . Syphilis is common among the out-patients in all district dispensaries. . . . . "Scurvy, measles, chicken-pox, mumps, whooping-cough, are almost unknown, or at least are not "recorded as fatal."

23. Speaking generally, the registration in Assam is improving so far as numbers are concerned, but it presents one singular anomaly, that with a registered death-rate of 29·37 per 1,000, no less than 82 per cent. of this rate is attributed to the four epidemic or endemic diseases, "cholera," "small-pox," "fevers," and "bowel complaints." It need scarcely be said that such a proportion is not at all a likely one, and that it shows both defect in numbers, and unskilled diagnosis.

It may, however, be accepted as a practical conclusion from the year's disease history that the sanitary work most needed in Assam is that which will best cope with the strong epidemic liability of the population. What this liability ends in is stated by the Sanitary Commissioner in the following paragraph of the present Report. He says, "Since I have been in the province nothing has "struck me more than the few and rare appearance of men and women just beyond middle age, and "very old ones. But after reading the statistics of epidemic diseases, and learning the conditions of "life in Assam, one ceases to wonder that few should survive so many dangers for 50 years."

24. The sanitary explanation of this state of the case is simple enough, and is as follows. After escaping the perils of infancy and childhood, during which many perish, the apparently "fittest" to survive and form the future backbone of the population are those who attain to adolescence, but their actually becoming "the fittest" by no means follows from their having survived the dangers of early ages, because, as a matter of fact, they become liable at this period to fatal attacks of epidemics, and the most promising and most productive periods of human life are precisely the periods yielding the largest per-centages of epidemic deaths, as well as of epidemic cases which depress the subsequent vital sources of all who suffer. Hence the "unfittest" are those who survive, and the "survival of the fittest" can only be rendered a fact, in human history at least, by destroying the causes of epidemics. This survival is hence a conditional and not an absolute fact, and the Sanitary Commissioner has shown what are the results of attempting to ignore the condition, which is not peculiar to Assam. It is universally binding, and hence the prevention or removal of local causes of epidemics, and the consequent survival of adolescents through the epidemic ages results not only in effective present working power, but in continuing the stream of life into mature old age.

25. *Sanitary works (Civil).*—After the preceding discussion, it is scarcely necessary to discuss the year's sanitary works, because the statistics show how little has been done. In the Report is given a list of 20 towns, unions, stations, and municipalities, with the amounts expended in each for sanitary purposes under the following heads:—

	R.	A.	P.
Drainage	6,435	12	11
Water-supply	3,880	13	10
Conservancy	18,347	2	1
Disposal of dead	122	4	0
Roads and culverts	27,630	14	4
Markets and slaughter-houses	3,570	4	9
Village sites	—		
Other sanitary improvements	3,013	13	11

There was thus an outlay in 1884 for all sanitary purposes, including 2,763*l.* for roads and culverts, of about 6,300*l.*, and for special sanitary work the expenditure was thus only 3,637*l.*

But even this amount was unequally distributed among the 20 population areas. Thus in nine there was no outlay for drainage. In 12 there was no outlay for water-supply. Three were not provided with funds for cleansing. In only three was there money expended on the dead. In 10 there was no outlay for markets and slaughter-houses, and nothing was spent in improving village sites.

26. The notes of the Sanitary Commissioner on the local expenditures are mainly devoted to telling us what has not been done, and the consequent deplorable sanitary condition of many localities.

27. A few abstracts will show what is the present sanitary state of the towns. For example, he repeats Dr. De Renzy's statement, that "in some places people bury their dead in their own houses "and compounds, and in one place, he says, 'I saw the dead left exposed to carrion birds.'" One Civil Surgeon reports that he saw a cholera patient being buried after death inside a house. Of course, the remedy for such practices is well known, only it is not applied. The water-supply allotment of 388*l.* is too small to have made any difference in the present system.

Taking the towns individually, the Sanitary Commissioner states that on visiting Dhubri last December he found marks of improvement, but that much remained to be done for "foul drains, "stagnant tanks, uncleansed privies, and festering refuse." In this town the municipal authorities have actually permitted the digging of enormous pits for brick making, which will of course become potent disease causes. This practice has in times past done incalculable mischief to the health of towns and villages all over India, and should be summarily forbidden. Indeed, one of the most obvious sanitary improvements required all over India is the filling up of all these pits. It is satisfactory to know, however, that the emigration coolie depôts were in excellent order, "and every "sanitary detail most carefully watched," and that the Vice-Chairman of the Municipality "interests himself greatly in sanitation, and knows thoroughly what is desirable.

Goalpara.—This is a small town with 6,697 inhabitants. Its death-rate in 1884 was 41·95 per 1,000, which appears to be a low rate, as the previous five years' average is given at 56·14 per 1,000. Its water-supply is what it was, but in regard to the drainage there is the following statement:—"The extensive drainage scheme is complete as to the main channels, and has worked for the last "two years. It seemed to me to have done no good. It has cost Rs. 10,000, but the results seem "very inefficient. The extent of low wet marsh land, of stagnant bhils and tanks, were there as "of old, and I could not see that any delivery current towards the Hanslar jheel had been effected." This would appear to show that the work was one not adapted to the case. Any way, the town and its vicinity appears still to stand in need of drainage.

28. The Sanitary Commissioner has placed in the same line the two following facts, as if they stood to each other in some necessary sequence. "The conservancy of the town cost Rs. 81 only, "and the dispensary Rs. 540." Such co-related facts have occurred before in the beginning of sanitary improvement, and in order to enforce the lesson we may cite the following analogous case of a fever-stricken English town, on which an excellent sanitary report was made very nearly a century ago.

This report was acted on in the beginning of the present century by the municipality, and a Bill for improvement was brought into Parliament, which was, however, defeated by the parishioners, who nevertheless laid a rate of 9*d.* in the pound to build a fever hospital, and provide a pauper graveyard to bury the dead. But this was not the worst, for the local fever causes went on unchecked and still manifest their presence after enormous outlay for their removal. The lesson, of course, is that sanitary work is essentially preventive in its nature, while dispensaries and fever hospitals are costly palliative expedients. Sanitary work requires forethought and skill, while the palliative measures only require money, which is also needed for sanitary work. But the difference is that sanitary expenditure, if properly applied, is in its nature accumulated capital, while relief work is wasteful outlay, so far as ulterior advantages are concerned.

In Goalpara every 30 inhabitants have their cleansing done at the cost of one penny per annum, and we need not wonder that the dispensary costs 54*l.* a year.

29. *Kamrup.*—The following passage from the Civil Surgeon's report refers to a very common disease cause in India, and one we have often referred to:—"Cholera was most persistent in a cluster "of houses on the southern bank of a foul tank in front of the Judge's house. The exhalation from "this tank is so bad at certain seasons of the year that even passers by suffer severely from breathing "it. The water is simply putrid (the river is not far off), yet is used for domestic purposes by the "people living near. I feel confident that when these foul tanks are filled up, there will be a great "improvement in the health of the town." Now, here is a case in which there would be no hardship and a great advantage in suppressing what is simply a dangerous nuisance.

The new waterworks for Gauhati "have been greatly delayed, and the "district officer is unable to "say when they are likely to be completed." Not a very satisfactory state of matters.

Barpeta, a town of 13,758 inhabitants, and a death-rate of nearly 4½ per cent., spent Rs. 250 on dispensary repairs, which were no doubt necessary. But "no money was allotted to water-supply, "disposal of the dead, vaccination, markets, &c."

"The conditions under which these people live, the severe epidemic outbreaks they experience, "their bigotry and opposition to reforms," have been frequently dwelt on.

Tezpur is a coolie depôt, "under close sanitary supervision." Nevertheless, out of 3,701 coolies and dependents who had passed through it, five had died of cholera.

Mangaldai is a village of 692 people, of whom 12 died of cholera and 23 of fever. There was one death from bowel complaint. There were in all 38 deaths, or 54·91 per 1,000. In this case 36 deaths were due to epidemic diseases, one death to snake-bite, and one cause unknown. We are told, regarding this place, that "the water-supply is always bad, and this year, owing to scanty rains, it has "been worse. Cholera, small-pox, fevers, recur periodically." Then let a proper supply be introduced, and the place otherwise improved. For so small a place, ten deaths would have been a probable loss under good conditions.

Nowgong "has many natural advantages," but a death-rate in 1884 of 56·96 per 1,000, a considerable part of which, however, is made up of deaths in the dispensary and among prisoners. Out of 4,248 inhabitants, it had a fever death-rate of 11·29, a bowel complaint death-rate of 14·36, and a cholera

death rate of 16·95 per 1,000, hence its epidemic death-rate was 42·60 per 1,000. So far as these data lead us, this town stands in need of cleansing, surface drainage, and water-supply

Sibsagar.—This town of 5,868 inhabitants and a five years' death-rate of 25·05 per 1,000, which in 1884 had fallen to 19·24 per 1,000, of which 1·70 was due to cholera, and 5·45 to fevers. This town had been actively improved by providing latrines, cleansing, and a good supply of water.

These are the chief points in the reports on Bramaputra towns.

30. The towns in the Surma valley present much the same sanitary defects, such as want of proper drainage, defective cleansing, impure water.

The Sadr town, Sylhet, appears to have an inactive municipality, with an average five years' death-rate of 31·58, and a rate for 1884 of 31·99 per 1,000. The death-rates would indicate considerable quiescence in the matter of sanitary work. We are told, indeed, that little material advance has been made. "The public and private latrines are neglected beyond all description, the uses of tanks "for washing, bathing, and drinking are still common, burial ground beyond municipal limits are "not yet enforced, overgrown and noxious vegetation increasing, and the drainage entirely "insufficient." This town has 14,407 inhabitants, and an income of Rs. 28,290, of which Rs. 13,487 were set apart for sanitary work, or less than a rupee per head, and the Vice-Chairman of the municipality reports that "the limited income of the municipality is the principal obstacle to all "improvements." Now, as we have seen, the Sanitary Commissioner has pointed out the chief improvements required, and not one of these requires the execution of works or any excessive outlay. As has been proved in other cases, sufficient improvements can be carried out at very small outlay, but this requires what is far more important than money, namely, efficient active work. Can it be said, on the facts stated by the Sanitary Commissioner, that the present income could not answer, or that any added amount would ensure the work being done. We doubt whether affirmative replies could be given, so that, in our view, the municipality should be required to abate the nuisances of which the Sanitary Commissioner complains. Let them manage their income, such as it is, to this end, and see that the work is done, and they will make more real progress by acquiring sound habits of making the best of their means than by calling for help from outside. This remark applies to most other local sanitary administrations in India.

31. Before concluding this Memorandum, we are desirous of calling attention to the present sanitary condition of tea garden coolies, dealt with in a separate Appendix to this Report.

It appears that the mean population in these gardens amounted to 260,758, as we have already stated. This number, however, includes women, children, men of working ages, infirm and old people.

In the course of the year there were 8,604 births among them and 10,853 deaths, yielding a death-rate of 41·62 per 1,000. This rate can scarcely be compared with the general Assam rate, 29·37 per 1,000, because the general registration is defective. The town rate, which may be supposed to be better recorded, was 32·09 per 1,000. This rate would place the tea gardens in an unfavourable sanitary condition. But then we have higher rates in individual localities, such, for example, as 49·67 per 1,000 among a population of 436,642 in Goalpara district, and 42·23 per 1,000 among 13,758 people in Barpeta town. It will thus be apparent that the statistical information supplied by the gardens is defective, because the population (only part of which is engaged doing work for the companies) is treated statistically in one group. It would hence scarcely be fair to charge the high death-rate against the management. What is wanted is classification and separation of the workers from the general population, and allowance should also be made for children and old non-workers in the mortality returns. All we can do at present is to state our opinion that in those groups of population engaged in the tea gardens the death-rate is excessive, while the statistics appear to show that the losses in the case of communities under the immediate supervision of European planters and their agents are greater than the average of other groups of population, a fact which ought to lead to greater care over these poor people.

The facts have received the earnest attention of the sanitary and other authorities, and the causes appear to be the following:—

First, the change of conditions and habits among the immigrants.
Second, unsuitable food and bad cooking.
Third, defects in drainage and water-supply.
Fourth, general inattention to sanitary requirements of dwellings and house necessaries, including bedding.
Fifth, drunkenness.

Now it is clear that, whatever may be the mortality among the workers, we have here a case in which a great body of people is removed from home, placed in new conditions, and there is plenty of experience to show that high death-rates are certain to result unless the surroundings are properly attended to. The mere fact that there is "terrible mortality among the new arrivals" shows this. Hence the whole question is a purely administrative one, and the result to be aimed at is simply to see that the conditions of life of these working people, removed from their own localities, are adapted to the change. Such appears to be the view of the authorities, and we would strongly advise that this view be acted on. The subject is not a new one. It has been thoroughly discussed, and what is wanted is greater activity in bringing about the necessary reforms.

32. The same Appendix gives an account of another year's experience of cholera among immigrant coolies on board river steamers, and the general question of its causes and remedies may be considered as solved. There might, indeed have been no question, if the very one-sided cholera water etiology had not been put forward, to exclusion of other predisposing causes. In our last year's Memorandum it was stated that coolies arriving at Dhubri were to be forwarded in mail steamers making quick

voyages, instead of by the usual slow means of transit; the presumption being that whatever risks were incurred on the river would, of course, be diminished by shortening the voyage. It so happens that the first year of this improvement was attended by a death-rate of 2·6 per 1,000, the lowest on record. This death-rate for a voyage of four or five days is, of course, enormous, but in 1878 the rate was 33·8 per 1,000 for a 16 days' voyage. The Sanitary Commissioner attributes the improvement to the good sanitary arrangements on board mail steamers, which, moreover, are not allowed to carry above 175 immigrants on board; cleanliness is observed, the cooking is good, "the latrines are "models of what such conveniences ought to be," and the cubic space and area are "sufficient;" there is good water and suitable hospital accommodation, and he considers that "the protection from "inclement variations of temperature is all that is necessary."

We have already strongly insisted on the importance of this consideration, especially at night, and until it is supplied the real death-rate due to river passages will not be known.

The Dhubri depôt, from which immigrants are now mainly embarked, is reported to be in excellent sanitary condition, but it appears to be too small, for coolies had to be sent on board slow craft to make the long voyage. This subject is of importance in relation to further extension of tea gardens, requiring a large increase of labourers. There is no information about immigrants to the Surma valley.

Lastly. We have had much satisfaction in former years in noticing improvements in water-supply of several towns in Assam, but although the present report gives a very full statistical account of the year's health conditions, the Government of India has pointed out its real defect in the half line in their Resolution on it, "The record of sanitary improvements is small." We are glad however, to see from the proceedings of the Chief Commissioner that there is every desire to forward improvements if means were available. We have already stated our view that more activity in the localities themselves in forwarding the work, even with the means at disposal, might very well be shown. The people should learn that in small places whatever is required for protecting health ought to be done by the people themselves, and that, if they do not choose this course of action, they must pay somebody else to do their work. This ought to be the duty of every municipal government.

Villages, of course, require a separate treatment, such as we have laid down in our "Suggestions."

16th April, 1886.

No. 10.

Memorandum of the Army Sanitary Commission on the Report of the Sanitary Commissioner of British Burma for 1884.

1. The population on which the vital statistics of Burma are calculated in this report for 1884 is assumed at 3,653,620, and as the registration is still imperfect, the year's statistics are only approximations to the truth. All that can be safely deduced from them are the numbers of births and deaths entered on the registers, but as will be presently seen the ratios are quite unreliable.

2. In 1884 there were registered the births of 42,747 males and 40,036 females, together 82,783, showing a birth-rate on the assumed population of 22·66 per 1,000.

3. The deaths registered in the same year were, of males 39,079, of females 30,155, together 69,234, yielding a death-rate of 18·95 per 1,000. Although neither rate represents the facts, we may accept the result that in 1884 the birth-rate registered exceeded the death-rate registered by 3·71 per 1,000 for the entire province. But when the 20 towns are taken by themselves, their conjoint population of 425,775 yielded a birth-rate of 23·28 per 1,000, and a death-rate of 36·65 per 1,000, showing a decrease of 13·37 per 1,000, which, if correct, would represent a loss of town population of 5,693 during a single year. It may be safely inferred that the year's death-rate is much nearer the truth than is the birth-rate, and the figures appear to show that the defect in this case has been in birth registration.

4. It is unnecessary for our present object of calling attention to the need of improving the registration of births and deaths to pursue the subject further. The authorities are fully alive to present inaccuracies, as well as to the difficulty of dealing effectually with them; but the facts show anew the importance of pressing forwards the improvements required in this fundamental part of public health administration.

5. If the year's statistics are unreliable as a whole no great dependence for sanitary purposes can be placed on the statistics of disease. We must, however, deal with them as they are given in the report. They stand as follows:—

Diseases.	Deaths.	Deaths per 1,000.
Cholera	5,515	1·51
Small-pox	6,102	1·67
Fevers	29,534	8·08
Bowel complaints	3,719	1·02
Injuries	522	·14
All others	23,862	6·53
All causes	69,234	18·95

6. Following the same order, we shall give briefly such information as the report contains under each head of mortality, beginning with cholera, from which 640 deaths were registered in 1872, and since that year the yearly registered mortality has been as follows:—

Years.	Deaths from Cholera.	Years.	Deaths from Cholera.
1873	8,109	1879	1,828
1874	960	1880	2,638
1875	761	1881	5,289
1876	3,678	1882	7,177
1877	7,276	1883	2,456
1878	6,762	1884	5,525

These figures, if reliable for the 12 years, would appear to show that epidemic cholera in Burma has periods of increase followed by rapid decline, and more gradual augmentation. But in a long narrow scattered country like Burma nothing very definite can be predicated in this matter for the country as a whole, although it is not unlikely that the different regions of it, if the statistics were accurate, would have each its own topographical cholera history. This fact, indeed, is indicated by the cholera history of 1884. Thus, in the Northern or Arakan division there was no cholera in January, February, and March. At the Southern end of the country, in Tenasserim division, there were only a few scattered cases, except in the months of November and December. The sea coast divisions suffered little during the earlier months of 1884, while the weight of the epidemic fell on Pegu and Irrawaddy divisions in the river deltas. Taken over the whole country, mortality was as follows:—

Months.	Cholera Deaths.	Months.	Cholera Deaths.
January	57	July	1,119
February	85	August	687
March	321	September	522
April	445	October	522
May	408	November	449
June	423	December	534

Although Arakan division suffered very little until after July, its death-rate when the epidemic arrived was the highest divisional death-rate, namely, 2·11 per 1,000, while Pegu and Irrawaddy, in both of which cholera prevailed every month, had death-rates of 1·36 and 1·99 respectively.

7. Within the divisions themselves the epidemic was made up of sparse village outbreaks.

Out of 843 circles of registration 706 escaped the disease altogether, and all the deaths were returned from 227 villages, leaving 14,564 unaffected. Generally the towns suffered more than the villages in the proportion 2·68 per 1,000 for the former and 1·51 for the latter. In Arakan division, which had a cholera death-rate of 2·11 per 1,000, Akyab district had a rate of 1·70 per 1,000, but Akyab town had a rate of no less than 6·86 per 1,000, showing clearly the influence of bad locality. The town of Prome yielded a cholera death-rate of 7·08 per 1,000, while Prome district had a rate of 2·39 per 1,000.

The highest rate of the year was returned from Pantanaw town. This was 3·58 per 1,000, a rate which exceeded that of Irrawaddy division, in which it is situated, by 0·89 per 1,000. Hanthawaddy district, in which the capital, Rangoon, with a population of 134,176, is situated, returned a cholera-rate of 0·45 per 1,000, while Rangoon had a rate of 0·52 per 1,000, in spite of its large population. Apparently the comparative exemption of the city was in part at least due to sanitary work. The general result of the year's experience may be said to be that, during cholera periods, two factors are included, the epidemic over which we have no control, and local insanitary conditions which we can remove or mitigate. It is the same experience which is reproduced in every outbreak of cholera, and it carries its lesson with it.

We shall return to this aspect of the question while discussing the sanitary state of the towns. But in the meantime it should be stated that, out of 20 towns with an aggregate population of 425,775, all returned cholera deaths with two exceptions, Mergui and Toungoo, whose conjoint population was 25,832, so that a town population of about 400,000 yielded 1,139 deaths. On the other hand the country population, which yielded the village deaths, was 3,227,864, living in 14,611 villages, of which 227 only suffered. We have no means of estimating the population of these 227 villages. All we know is that they yielded 4,376 deaths, or about 19 deaths per village.

8. *Small-pox.*—The second disease on the list is small-pox, the deaths from which were 6,012, or above 500 more than the deaths from cholera. Of these small-pox deaths 1,088 took place in children under one year of age, and 4,061 from that age and under 12. Hence there were 5,149 deaths, or about 85 per cent. of the total mortality, at ages when the protection under an efficient system of vaccination ought to have been more or less complete.

9. The past history of small-pox mortality in this province has been as follows since 1872, in which year 845 deaths were registered :—

Years.	Small-pox Deaths.	Years.	Small-pox Deaths.
1873	1,416	1879	2,297
1874	1,191	1880	5,402
1875	752	1881	1,766
1876	1,335	1882	770
1877	1,230	1883	675
1878	1,408	1884	6,102

It will be seen that the largest number of deaths registered was in 1884, and we have just seen how heavily the mortality fell on the younger ages, a sure test of inadequate vaccination arrangements. From data in the Report we learn further that during the last eight years about 65 per cent. of the small-pox mortality had been registered among children under 12 years of age.

10. The monthly deaths in 1884 were as follows :—

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January	194	July	561
February	621	August	460
March	794	September	367
April	740	October	272
May	765	November	255
June	714	December	339

This abstract shows the highest mortality from small-pox during the hot months. The epidemic was present in all the districts with one exception, and the affected registration circles (146 out of 343 in the province) were scattered over the districts, except in the exempted one referred to. But the epidemic law was strictly followed, for the entire year's mortality was returned from no more than 149 population groups out of 14,811. All the 20 towns with two exceptions, Tonghoo and Mergui, suffered, but as these two towns are the same two that escaped cholera, the probability is that this apparent exemption was the result of bad registration.

So far as can be estimated from the registered deaths, the epidemic was much more severe in town than in country circles. The towns yielded a very high rate, namely, 4·86 per 1,000, while the country rate was 1·67 per 1,000.

11. As there is defect in the birth registration, we cannot estimate with any degree of accuracy the influence of vaccination on small-pox mortality. Taking the data in the Report as the best available, the births actually registered in 1884 numbered 82,783. But the vaccinations under one year were only 9,673, or fewer than an eighth part of the registered births, which were far below the real number. Between one and six years, there were 35,481 vaccinations, but this number cannot be counted against the actual births. The total successful primary vaccinations at all ages were 69,853, so that including successful re-vaccinations, and while the registered births amounted to 22·66 per 1,000, the successful vaccinations of all kinds and at all ages were 19·95 per 1,000 of the population.

12. The vaccination staff of the year stood as follows :—

Superintendent-General	1
Superintendents of Circles	19
Deputy Superintendents of Circles	1
Native Superintendents	5
Vaccinators :—	
1st class	20
2nd class	38
Servants	3
Total staff	87

The practical result of the year's vaccination work is that great improvements are needed before the infant population can be considered safe from this scourge. The facts are duly estimated in the present Report, and all we can do is to repeat a recommendation we have often made, that the best results of vaccination must be sought, not by increasing the number of operations at the higher ages, but by directing effort mainly to securing the vaccination of infants.

13. *Fevers.*—The following table gives the monthly average fever mortality, together with the monthly average climatic elements for 1884 :—

Months.	Fever Deaths.	Rainfall, Inches.	Humidity.	Mean Temperature.		
				Max.	Min.	Range.
January	2,205	·11	89·86	88·75	61·29	22·66
February	2,125	·29	84·50	87·09	59·81	27·28
March	2,026	·97	86·50	93·10	68·00	25·27
April	1,712	·65	86·57	96·44	72·71	23·73
May	1,794	2·00	87·21	93·27	73·80	19·46
June	1,994	23·43	88·71	88·72	73·80	15·93
July	2,974	36·31	85·50	86·28	73·92	12·36
August	3,184	27·06	85·79	86·00	73·97	12·03
September	3,008	23·11	85·21	85·92	73·71	12·21
October	2,583	7·80	79·14	88·57	72·15	16·42
November	2,736	2·62	73·52	86·45	67·49	18·54
December	3,131	—	64·43	83·59	60·30	23·29

The fever deaths in this table are those registered, but the climatic data appear to have been obtained by adding up the monthly averages and dividing the sum by the number of observing stations. In this way only a rough general estimate of the relation of climate to fever deaths month by month can be arrived at. The facts are relative, but not absolute. They nevertheless show that high daily range exerts a certain influence on the fatality of fever, just as rainfall does.

We have not the means of instituting similar comparisons for each of the districts, but we can place side by side the fever mortality and the rainfall in each division as follows :—

Divisions.	Average Rainfall, 1884.	Fever Deaths per 1,000.
	Inches.	
Arakan	204	12·29
Pegu	78	7·84
Irrawaddy	78	7·86
Tenasserim	147	5·77

But these average rainfalls are made up of large and small amounts, and do not admit of being used as ratios. We may, however, state, as a matter of fact, that in 1884 Akyab district had a rainfall of 196·83 inches and a fever death-rate of 12·69 per 1,000, the highest rate of the year. Thyet Myo had a rainfall of 33·47, and nevertheless its fever rate was 10·21 per 1,000. Take again Tavoy district. It had one of the lowest fever-rates of the year, namely 5·33 per 1,000, and yet its rainfall was 165·72 inches. This occurrence was not accidental, for the mean rainfall of Tavoy for the five previous years had been 210·91 inches, actually the highest five years' average of any district in Burma, while its mean five years' fever-rate had been 4·89, within a small fraction of the lowest district mortality of the same years. These facts throw light on the relation of rainfall to fever. At first sight it would appear that the more rain the more fever was the rule in Burma. But this is really not so, and the causes of fever mortality must be sought elsewhere.

14. There are whole districts of country in which the fever-rate is remarkably low, that is if the registration could be depended on, and it is not improbable that some of the mortality may be due to the usual local insanitary conditions, as well as to malaria. The Report does not help us much at arriving at these conditions. But the town rates averaged 10·33 from fevers and the country rates 7·78 per 1,000, pointing to the presence of fever causes in the towns.

15. *Bowel complaints.*—Deaths registered under this head numbered 3,719. They were all returned from 131 villages, situated in 118 registration circles. It is highly improbable that the registration in this instance affords any data worth discussion.

16. *Injuries and all other causes.*—There were 522 deaths from "injuries," and 23,862 registered under the head of all other causes, so that no account could be given of a third part of the total deaths of the year.

17. *Sanitary condition of the towns.*—Under the head of "Sanitary Works (Civil)," there is a certain amount of information given which enables us to form an estimate of the present sanitary state of the chief population groups. The 20 towns contain a population of 425,775, their average death-rate in 1884 was 36·65 per 1,000 from all causes, or above six per 1,000 over the preceding five years' average. The facts tell against sanitary progress. The five years' rate was 27 per 1,000, a rate exceeded in several of the towns, and which of itself would argue great want of sanitary care. Usually in these Eastern towns progress in improvements is attended by tangible reduction in the death-rates, but in these Burmese towns we have a large increase in 1884. Moreover, registration ought to be more or less reliable in the town circles, so that the evidence apparently leads us to conclude that there has been some falling off in sanitary work.

18. The town death-rate of 36·65 per 1,000 was made up as follows:—

Cholera	2·68	per 1,000
Small-pox	4·86	„
Fever	10·33	„
Bowel complaints	3·48	„
Injuries	0·31	„
All other causes	14·99	„
All causes	36·65	„

Here we have diseases of the so-called zymotic class, yielding a death-rate of 21·35 per 1,000, a rate for which there must be some local reason.

19. Rangoon, the capital, with a population of 134,170, had a death-rate in 1884 of 38·08 per 1,000, against a previous five years' average of 29·87 per 1,000. Of this rate of 1884 only 0·52 was due to cholera. There was a severe epidemic of small-pox, during which 884 of the people died, or 6·59 per 1,000. There were 1,861 deaths, or 13·87 per 1,000, from fevers, and 4·08 from bowel complaints. Part of the excess of mortality was due to small-pox. The cholera mortality, although low, exceeded the Hanthawaddy district rate, which was 0·41 per 1,000.

Rangoon presents a good instance of a town in which the element of impure water has been eliminated. It is stated by the Medical Officer to have been derived as during the last year for the most part from the Kokkaing and Royal lakes, and is "abundant, pure, and delicious." Whence came the cholera death-rate in excess of the surrounding country rate if the sole cause of cholera is bad water? The new water-supply is only one of the improvements which we are glad to see are in progress. The large influx of water has directed attention pointedly to means for its removal from the town site, a measure of absolute necessity, and a drainage scheme besides the existing surface scheme was under consideration. It is described as follows:—"An elaborate scheme for the drainage "of the town on Shone's hydro-pneumatic system has been prepared by the Engineer, and is under "the consideration of the Committee. The estimated prime cost is 170,346*l.*, and if a supplementary "high pressure water-supply is adopted at the same time 180,035*l.*" No details of this proposal are given, and we are unable to deal with it. Drainage of private houses was in progress while surface drains were being extended. Conservancy has been attended to as usual, and 25,000 tons of street sweepings had been deposited and covered on low-lying ground, whereby about 12 acres had been reclaimed, not, as we trust, to be built on. Night-soil to the amount of 42,500 tons from an area occupied by 60,000 persons had also been removed. This is all in the right direction, but the time appears to have arrived for the municipality with the aid of their health officers to inquire into the causes of the existing high death-rates, and in doing this to localize them, for it is more than probable that the town death statistics are unduly raised by the bad sanitary condition of certain areas, and information so obtained would enable sanitary outlay to be more efficiently applied. It would be most advisable that in this far off Eastern city a complete sanitary system should be agreed on after such an inquiry as we have suggested, and the worst districts first taken in hand.

20. *Prome.*—This town has a population of 28,813, and a very high death-rate, no less than 52·82 per 1,000, which exceeded greatly the five years' average of 34·86 per 1,000. Of the high rate of 1884 cholera yielded 7·08 per 1,000, small-pox 3·89, fevers 13·12, and bowel complaints 5·14 per 1,000. Hence the aggregate death-rate from diseases of the epidemic class was no less than 29·23 per 1,000, a ratio considerably in excess of what the death-rate from all causes ought to be in so small a population. Out of 1,522 deaths registered in 1884 no fewer than 842 were due to directly mitigable or preventible diseases; yet of this great loss of life no adequate account as regards its causes is given in the Report. Part of its water-supply is derived from tanks and wells, and is "very impure." The drainage has been improved, but it is expected that when the new scheme is carried out the drainage "will be very perfect." No account, however, is given of the scheme, and we can form no opinion about it. There appear to be cesspits behind the houses, and removal of night-soil by hand, to be afterwards trenched, is in use for household cleansing. When the population, its death-rate, and diseases are compared, it appears as if a careful and detailed inquiry and report were necessary to enable sanitary work to be properly directed in Prome.

21. *Shwedaung* has a population of 12,373, and a persistently high death-rate. Its five years' average was 41·40 per 1,000, which rose in 1884 to 45·10 per 1,000. Its death-rate from cholera was 3·88 per 1,000, from fevers 10·02 per 1,000, and from bowel complaints 9·54 per 1,000. There were only three deaths from small-pox. In this town the water-supply is bad, the drainage appears to be effected by surface cuts, and the cleansing staff, which, nevertheless, consists of 15 coolies and four carts, is considered to be insufficient. It would be advisable in this case to examine into the sanitary state of the houses and their water-supply; with so small a population, it seems not unlikely that the death causes may be local rather than general.

22. *Akyab*, with a population of 33,989, yielded a death-rate in 1884 of 39·34 per 1,000, or about 9¼ per 1,000 over the previous five years' average. There was no small-pox, and above half the year's mortality was caused by cholera, fever, and bowel complaints.

There appears to be something unfavourable to health in the local position of this town, besides defects in its water-supply and drainage. It appears as if the present surface work did not reach the causes of ill-health, while it is not unlikely that the more important evils may be found within the houses and compounds.

23. *Moulmein*, after Rangoon, is the largest town in British Burma, and had a population of 53,107. Its death-rate in 1884 was 32·31 per 1,000, and its previous five years' average rate was 20·92 per 1,000. The zymotic death-rate was 17·39 per 1,000. Moulmein is supplied with water by wells which dry up in the hot weather, and water has to be brought from the Attaran. There is only drainage by surface cuts, and the night conservancy is carried out by contract under inspection, and the night-soil is buried "when possible." Cesspits are also used.

24. These examples will be sufficient to show what is the sanitary state of the towns, and it will be observed that the more obvious disease causes are those connected with the state of the subsoil and wells.

The towns are now under local government, and while no serious objection can be raised against the existing sanitary procedure, it can scarcely be sufficient for removing disease causes. The safest way to lay a reliable foundation for dealing with these is to have the towns carefully examined with the death statistics in hand, to determine what should be done to begin with the worst localities. The facts, so far as they go, account for the epidemic mortality.

25. In the matter of sanitary works there is only little to record.

The whole amount expended for a year's sanitary work was Rs. 1,54,187, allotted as follows:—

	Rs.
Water-supply	84,365
Latrines	4,775
Markets	25,049
Burial grounds	9,498

The two last items, although very necessary in themselves, left no more than about 7,000*l*. for sanitary work properly so called. Of course not much could be done with this outlay. Generally speaking, water sources appear to have been cleansed and repaired, surface drainage cleaned out and extended, and other drainage improvements initiated. Conservancy appears to be the sanitary measure best carried out, but until the house cesspits and bad wells are closed and the public health protected, not by this or that expedient, but by consistent schemes of work carried out under the local authorities, the high epidemic death-rates in towns may be expected to continue.

26. As we have suggested, future sanitary inspections and Government endeavours should take this direction for the towns, so that the new authorities may be kept out of wrong grooves at the beginning of their work, but the towns contain only a small part of the population, and as the Government of India has stated in the 8th paragraph of their letter on this Report, "Nothing seems "to have been done during the year to improve the sanitary condition of the villages in the province, "nor were sanitary works of any magnitude undertaken in the towns, but it is satisfactory to observe "that some important sanitary projects were under consideration."

This passage resumes in a few words the present position of public health proceedings in Burma, and it is very necessary to see that any projected works are found in principle, and suited to the requirements of each locality, while the villages where epidemics have their origin are not neglected.

12th March 1886.

No. 11.

Memorandum of the Army Sanitary Commission on the Sanitary Condition of Rajputana for 1884.

1. The data in this Report consist of two separate groups. Those referring to the population of Ajmere and Merwara, which is stated on the Census of 1881 at 460,722, and those belonging to 16 Native States, the population of which at the same census was returned at 9,354,163.

Sanitary work in the first group is done more or less under the inspection of British officers, and in the Native States any progress may be said to be due to example, persuasion, and to a desire on the part of Native rulers to improve the sanitary condition of their subjects.

For Ajmere and Merwara we have data similar to those returned from other Indian Governments. But for the Native States the returns refer to vaccination and dispensary work and to jail statistics. Properly speaking, there are no sanitary statistics as yet, although the local authorities appear to be doing the best they can to afford information on the subject.

2. The following remarks will be chiefly confined to the sanitary data of Ajmere and Merwara.

As already has been stated, the population of these two provinces amounting in 1881 to 460,722, but the rate of increase is not known.

The population was made up of 57,809 Muhammadans, 400,337 Hindus, no Christians, and 2,576 of other classes. The births registered in 1884 were of males 6,749, of females 5,798, together 12,547, or 27·23 per 1,000 of the population, a ratio under the truth.

3. In the same year the deaths amounted to 5,827 males, and 4,597 females, together 10,424, equal to a death-rate of 22·62 per 1,000, also below the true rate.

4. There are 23 registration circles in the provinces, which yielded death-rates between 13·29 and 45·45 per 1,000. The registration is improving, as is shown by the total rate having increased from a five years' average of 21·84 to 22·62 in 1884, while during the same five years the differences in the circle death-rates were much greater than in the latter year.

5. The death causes of 1884 are enumerated as follows:—

Diseases.	Deaths.	Deaths per 1,000.
Cholera	227	0·49
Small-pox	958	2·06
Fevers	6,428	13·85
Bowel complaints	1,205	2·61
Injuries	207	0·45
All other causes	1,409	3·06
All causes	10,424	22·62

This abstract shows that although cholera prevailed in an epidemic form, its death-rate was the lowest of any disease rate of the year; that small-pox was four-fold more fatal than cholera, but that the chief losses of the year were assigned to fevers, which yielded nearly two-thirds of the mortality.

6. *Cholera.*—This disease appeared as a distinct and completed epidemic in the course of 1884, as is shown by the following monthly mortality:—

Months.	Deaths from Cholera.
May	3
June	5
July	136
August	72
September	11
Total	227

Of the 23 circles of registration, cholera appeared in 11, but its ravages were confined to 15 out of 739 villages in the States. The epidemic was almost confined to the eight circles of the northern or Ajmere division, or perhaps more correctly to Ajmere town, its suburbs, and rural circle. The population of these three localities amounted in 1881 to 71,084. The deaths from cholera were 175, and the death-rates were for Ajmere town 1·45, for the suburbs 12·45, and for the rural circle 0·41 per 1,000. It is quite evident, therefore, that the full force of the epidemic fell on the suburbs of Ajmere, where, out of 8,592 inhabitants, 107 died of cholera.

We shall next abstract the account given of this occurrence.

7. The first case of the Ajmere outbreak took place in a woman lodging in a hut in the suburbs of Ajmere on the 25th May, who had arrived the day before from Aligarh, "where people were "suffering from cholera." (Aligarh district contains a population of 1,021,187, among whom there were three deaths from cholera in February, two in March, one in April, and 52 in May.) There was no other case until 15th June, when two were attacked, followed by four others, near the Delhi and Madar gates of the city. The disease remained quiescent until the 2nd July, when it burst out, and before the end of the month 253 persons were attacked and 114 died. In August there were 84 cases and three deaths.

8. The deaths in towns were as follows:—

Ajmere, 59 in June, July, and August.
Pisangan, 3 in July.
Nasirabad, 8 in August and September.
Nyanagar, 20 in May, July, and August.

The dates show that the epidemic covered nearly the entire area of Ajmere and Merwara, but it also covered the Native States, and the total registered cholera mortality for Rajputana, including Ajmere-Merwara, was as follows:

	Deaths.
May	84
June	145
July	485
August	473
September	107
October	3

The Native States of Central India suffered at the same time, and before those of Rajputana. There were fatal cases there in January, March, and April.

The mortality for the whole group of States in Rajputana and Central India was 2,315. The history is that of an ordinary cholera epidemic having no relation to the disease in Aligarh or anywhere else except an epidemic one.

9. The most important fact connected with the cholera epidemic of 1884 was its severity in Ajmere and its vicinity, especially in the suburbs, and this has been no new experience, although the great cholera death-rate of 1884 points apparently to the danger of severe periodic outbreaks beyond the usual mortality. The rate of 1884, as we have seen, was 12·45 per 1,000, while the previous five years' average rate had been 1·63 per 1,000 for the suburbs, and 1·50 per 1,000 for Ajmere rural circle, or nearly tenfold the quinquennial average for other parts of the provinces. There must, of course, be some reason for this great difference in liability to cholera, but no reason for it is assigned either as regards locality, climate, or sanitary conditions. We have alluded to this point in previous Memoranda, and it may be again suggested whether skilled inquiry may not throw some light on it.

10. We, of course, take it for granted, in the absence of definite information, that the sanitary state of attacked houses and localities does not differ much from those of other groups of Indian population, but when epidemics are more fatal in some districts than in others in the same province it is only reasonable to expect some account of the causes. As regards the Native States, the Surgeon-Major remarks that, "it is not surprising to find that, though individuals here and there dimly "perceive the importance of hygiène, the people generally in the Native States are indifferent to it." It is the same case all over India, and it can only be met by bringing the influence of the first class to bear on the second. In the Native States much might be done by the rulers if their attention was properly directed to the subject.

11. *Small-pox.*—In Ajmere and Merwara there were 948 deaths from small-pox registered, of which 358 were under one year of age. The death-rate was 2·06 per 1,000, or nearly fivefold the death-rate from cholera. The previous five years' average rate was 1·71 per 1,000, or eightfold the corresponding death-rate from cholera.

Cholera in 1884 took the form of an outbreak in the middle of the year, but small-pox deaths were registered in the following monthly numbers:—

Months.	Small-pox Deaths.	Months.	Small-pox Deaths.
January	88	July	61
February	77	August	21
March	178	September	12
April	243	October	11
May	207	November	6
June	66	December	29

It will be observed that the cholera outbreak began when the small-pox epidemic was on the decline. Cholera was reported from 11 registration circles, while small-pox deaths were registered in 21 circles out of a total of 23 in the provinces. There was the same difference in the proportion of population groups attacked. Cholera appeared in 15 towns and villages out of 739, but small-pox covered a tenfold greater area, or 151 population groups. The two diseases, moreover, did not attack the same places with equal intensity. Ajmere, its suburbs and rural circle, which suffered so severely from cholera, yielded only 64 deaths from small-pox; while Binai and Mazada, which escaped cholera altogether, had 337 fatal casts of small-pox. Again, the whole of the south-eastern division, which includes Merwara, returned 20 deaths from cholera, whilst its small-pox mortality was represented by 382 deaths.

So far as the registration can be depended on, the two epidemic diseases had quite distinct histories, without any relations to each other.

12. *Vaccination.*—In Ajmere and Merwara this service was carried out by six vaccinators, and 3,982 persons were successfully vaccinated. An unusual proportion of operations are returned at young ages, for there were 1,976 vaccinations under one year of age, and 1,930 over one year and under six; so that nearly the whole number were young children and infants. The number of registered births in 1884 were 12,547, so that the vaccinations under one year were fewer than a sixth of the births, showing that considerable extension of the vaccination service is required, and mainly in the direction of the infantile ages.

13. *Fevers.*—Endemic diseases registered under this head were by much the most fatal death causes in 1884. All the 23 registration circles in Ajmere and Merwara, and all the villages, 739 in number, with two solitary exceptions, returned fever deaths, numbering in all 6,428, or in the high ratio of 13·95 per 1,000, against a previous five years' average of 11·72 per 1,000.

14. The following were the registered monthly deaths in 1884:—

Months.	Fever Deaths.	Months.	Fever Deaths.
January	452	July	487
February	467	August	603
March	460	September	704
April	378	October	699
May	412	November	761
June	324	December	681

The year's numbers show the disease to have been mainly endemic, with a tendency to increase during the drying-up months of the year. There is no information in the report on fever causes.

15. *Bowel complaints* were returned as death causes from 22 out of 23 registration circles, and from 352 population groups, or nearly half the entire number. The monthly distribution of deaths was nearly the same as in the case of fevers. They were 1,205 in number, or 2·61 per 1,000 of the population, against a previous five years' average of 2·23. The data do not call for remark.

16. Before discussing the present state of sanitary service in the provinces, we shall give a brief account of the disease history of the Native States.

There are 16 Native States in Rajputana, but returns of births and deaths were received from only three States, Jallawar, Burtpore, and Ulwar, and from five cities. The population supplying the data was 1,861,215, out of a total population of 9,354,163.

Registration is only in its infancy in these States, but still a beginning has been made, and, such as they are, the data have been collected and supplied voluntarily by the Native authorities. Births were registered in all the localities with the exception of Ulwar city. They amounted to 26,936 or 14 per 1,000 of the population.

17. The following deaths were returned:—

	Deaths.
Cholera	135
Small-pox	920
Fevers	12,430
Bowel diseases	2,390
Snake-bite	6
Injuries	425
All other causes	4,778
All causes	21,084

The death-rate on the registering population was 11 per 1,000. The highest rate, 39 per 1,000, was returned from Joypore city, which also returned the highest birth-rate, 31 per 1,000, both rates showing good registration work. The lowest death-rate was returned at 3 per 1,000, from Bhurtpore State.

18. There is very little information about the local causes of epidemic diseases in these States, and very little appears to have as yet been done for their removal. Not much, indeed, can be effected at present in the way of improvement, because the facts in vital statistics on which the necessity for improvement must be based can scarcely be said to exist. This circumstance shows the necessity of recognizing the work which has been done in this direction, and encouraging further progress. This, together with the spread of information among the Native authorities, appears to be all that can be done at present.

Vaccination in Native States.—Vaccination is carried out to a considerable extent in all the Native States. In 1884 the work was done by 74 vaccinators, and the *successful* operations returned were as follows:—

Under one year	71,202
One year and under six	52,515
Total at all ages	131,806

This total shows a large increase of operations in 1884 over the previous five years' average, which was 85,135 vaccinations per annum. We have no means of comparing the deaths from small-pox within the area covered by the vaccination, nor of estimating the relation of vaccinations under one year to the year's births.

Jails of Rajputana.—There is a single jail under British supervision in Ajmere, and 13 jails in the Native States, and the following abstract shows the relative sanitary state of each class for the last five years:—

Years.	Adjere Division.		Native States.	
	Number of Prisoners.	Death-rate per 1,000.	Number of Prisoners.	Death-rate per 1,000.
1880	484	10	2,806	48
1881	429	4	2,787	46
1882	495	26	2,662	36
1883	562	11	2,695	33
1884	583	3	3,020	45

If the class of prisoners is the same in Ajmere jail as in the Native jails, it is quite clear that there is much requiring improvement in the latter. The problem may be stated in the following question,

which is intended to lead the Native authorities to inquire into the subject. What is the reason that the death-rate in Native jails is fourfold the rate which has ruled in Ajmere jail? In 1884, 583 prisoners in Ajmere jails yielded two deaths, at a time when out of 3,020 in the Native jails 187 died. No sufficient account had been available as regards the causes of death in Native jails, except that 10 per cent. of them were due to malarial fevers, 17 per cent. to cholera, 20 per cent. to respiratory diseases, and 32 per cent. to diarrhœa and dysentery.

21. The mortality in Ajmere jail was made up of one death from apoplexy, and one from Bright's disease, neither of them jail diseases. The few facts we have been able to give regarding the death causes in Native jails show how large a proportion of the mortality in them was due to jail diseases.

22. *Sanitation.*—We have already quoted the Surgeon-Major's statement about Sanitation in Native States, and we may add to it the following paragraphs from his Report:—"A general, if a "somewhat unequal, advance has been made in sanitation by the Native States. This advance is "shown not only by an increasing interest in the cleanliness of the cities, but also by improvements "effected in jails and dispensaries."

This is well so far as it goes, but we have frequently shown that mere surface cleanliness is no test of sanitary condition. Disease causes are not on street surfaces, but in houses and house compounds.

In Jeypore the adoption of a complete system of conservancy is waiting provision for railway removal of town refuse at present in hand. Latrines and urinals have been erected. In two districts progress has been made in village sanitation.

"In Ulwar, owing to the intelligent interest taken in the subject by His Highness the Maharao Raja, the advance reported in previous years has, it is believed, been fully maintained."

In Jodhpore the conservancy staff has been re-organized, and several cities named are kept clean. This section of the Report is concluded by the remark that, "while therefore an enormous amount "remains to be done, it can be confidently asserted that something has already been effected, and "that progress is being made in the improvement of sanitation in Native States." Under these circumstances, perhaps the best advice we can give would be to place copies of our "Suggestions" in the hands of the authorities.

23. We have already called attention to the great loss of life from cholera in Ajmere and its suburbs as proving the presence of disease causes of intense activity in the latter. The improvements noticed in the present Report appear to extend to the town only. By the beginning of the present year, 1886, it was expected that the arrangements for the removal of town refuse by rail and provision of filtered water would have been completed. The Municipal Committee, it is stated, had "paid "considerable attention to sanitation, but progress is slow."

This may be taken as describing the state of most Indian municipalities, where, after all, the great want is not money, but energetic action.

24. In conclusion, we cannot compare the details given in this Report with those in the Reports of previous years without seeing that some improvements in the sanitary condition of the Rajputana States have been realized. The work is, and apparently will continue to be, carried on with considerable deliberation. But no doubt every encouragement will be given to the local efforts of individual rulers in perfecting their sanitary statistics, and using the information they will afford for saving life. The most unfavourable feature in the Report is the state of Native jails, which might be represented possibly with advantage to the local authorities. But, so far as liability to cholera is concerned, there appears to be plenty of work to do nearer home, in rooting out the epidemic diseases causes in Ajmere and its suburbs.

22nd June 1886.

No. 12.

MEMORANDUM of the ARMY SANITARY COMMISSION on the ADMINISTRATION REPORT of the MADRAS MUNICIPALITY for the 15 months from 1st January 1884 to 31st March 1885.

1. In our Memoranda on previous Reports of the Madras Municipality, we discussed the vital statistics of the population with special reference to the epidemic history of the city, and we were enabled, by the aid of local inquiries conducted by officers of the municipality, to show to what probable causes the high death-rates were due. These causes, indeed, appear to have been fully recognized in Madras itself, for on two separate occasions surveys and plans of works were prepared and submitted to the local authorities, but, apparently on account of the outlay required to give effect to either of them, they were not adopted. It was understood, however, at the time that there was still a hope that the city might be drained when the requisite funds were available.

2. At that date a new and better water-supply was introduced, but the available amount of it is still too limited to supply the whole population with a sufficiency for all domestic purposes, and a large part of the population is still dependent on bad or doubtful wells for their daily wants.

3. There was an active cleansing system in operation, as it still is, but it was and is confined chiefly to surface work, and within the last year or two we have quoted from Madras Reports the reports of medical inspections, showing the condition of house compounds, and the need of extending cleansing operations to them as well as to the streets.

4. The house sewage has been usually collected and removed by hand labour and carts, and this work appears to have been done with considerable efficiency in the divisions to which it has been extended, but the Report states that the fourth, fifth, and eighth divisions, which contain 17 villages, and an aggregate population of 115,388, "are yet without any system of house conservancy."

5. At different times underground sewers have been constructed here and there, chiefly as it appears to relieve localities from flood water, and there are no fewer than 12 sewage farms on which sewage of various kinds is in course of application for agricultural purposes, and a great improvement has been carried out recently in diverting sewage from the Cooum.

6. In default of a proper system of drainage and sewerage, a proposal was made to surface drain Black Town by side impervious drains, at an estimated cost of 85,000*l.*, of which 30,000*l.* has been already expended, so that it would be safe to include this drainage work along with the other sanitary works and measures as having exercised, possibly, some favourable influence on the public health.

7. But, besides these works, a quantity of bad unwholesome house property has been from time to time removed, and its disease causes along with it, and, in addition to these sanitary measures, Madras has a hospital and dispensary service, including a vaccination department, under five inspectors, 20 vaccinators, and eight probationers.

8. Altogether, therefore, Madras presents a not unfavourable amount of work of one kind or another, the object of which has been to diminish the sick and death rate of the population, and as the proceedings have been in operation for some 20 years, it is a not unfair question to ask what has been the result. The question is further justified by the fact that the course of improvement which has been adopted by the Madras municipality for a populous city has been based on principles opposed to those which have been acted on in localities similarly situated elsewhere.

9. In dealing with these questions we shall try to avoid all controversial discussion. The whole subject was fully discussed by us long ago. At present we have simply to deal with the facts, as these are presented by the vital statistics of the present Report. There is, however, a slight preliminary difficulty, arising from a change in the beginning of the statistical year from the 1st of January to the 1st April, which has to be dealt with, and objected to, as being contrary to all statistical rule and to the principles of uniformity in statistical periods everywhere else adopted. The key to the resolutions adopted at the International Statistical Congress of London many years ago was this very uniformity. In making up accounts of work and expenditure, the change is not of so much importance. But it is a cardinal principle in all public health questions that the year for vital statistics should be the calendar year, and not the official year, and the Report under review shows the inconveniences of this very change. Take, for instance, the following examples :—

—	Births per 1,000.	Deaths per 1,000.
Calcutta, 1883 - - -	17·6	30·50
Bombay " " -	18·79	29·12
Madras " - - -	41·20	39·20
Madras, 1884–85 - - -	39·80	49·20

Or take such numbers as these :—

Deaths, 15 months ending 31st March 1885 - - -	24,067
Reduced to 12 months - - - -	19,253·16

Of course, we cannot accept the 15 months' data or the calculated deaths, and we shall, instead abstract the numbers for the 12 months of 1884.

10. We hope, however, that in all future Reports the uniform calendar year may be reverted to, as we believe has been the case in Calcutta, where the official style had been tried. The questions involved are purely scientific in character, and have no relation to official convenience.

11. The population on which the ratios in the Report under review are calculated is that of the census of 1881, which was 398,777. The calculated births on this number were 16,133, and the calculated deaths for the complete year 1884 were 19,253·16, and this, when compared with the registered number of 1883, which was 15,487, shows an increase of 3,766 deaths during the calendar year 1884.

12. The death-rates among children were enormous. Above a third of the entire mortality of the year took place in infants under one year of age, and the deaths under five years were above 10,162, out of a population of 46,088, at the same ages.

13. The next abstract shows the death causes, but these figures include the numbers for 15 months, 1884–85 :—

Diseases.	Deaths.	Deaths per 1,000.
Small-pox	4,074	8·1
Measles	146	0·2
Fevers	4,863	10·7
Dysentery	2,158	4·3
Diarrhœa	1,301	2·5
Cholera	1,358	2·7
Injuries	109	0·1
Other diseases	10,473	20·9
Total	24,482	49·5

In order to keep the disease history in the proper order, however, it will be necessary to deduct under each head the deaths registered during the first three months of 1885, and the table will then stand as follows :—

Diseases.	Total Deaths in 1884.
Small-pox	4,064
Measles	138
Fevers	3,779
Dysentery	1,560
Diarrhœa	1,014
Cholera	1,198
Injuries	82
Other diseases	8,298
All causes	20,123

These figures would give a death-rate from all causes in 1884 on the census population of 1881 of above 5 per cent., and of this great death-rate, in a city which has been professedly under the hands of the improver for nearly a quarter of a century, upwards of 58 per cent. was due to epidemic and endemic diseases.

14. We may further call attention to the fact that the actual registered deaths in 1884 were 20,123, while by the back calculation method they were 19,253·16, or 870 below the truth.

15. It is clear from these data that the sanitary problem in Madras is mainly an epidemic one, while to understand it fully we shall have to carry the epidemic history for a number of years backwards. This is shown in the following abstract :—

Epidemic Diseases.	Total Annual Deaths.		
	1884.	1883.	Previous 10 Years' Average.
Small-pox	4,064	1,957	733·5
Measles	138	188	53·0
Fevers	3,779	3,470	3,229·2
Bowel complaints	2,574	2,264	2,327·9
Cholera	1,198	139	376·0
Epidemic causes	11,743	8,018	9,719·6
All causes	20,123	15,882	15,059·3

The registered facts show distinctly enough that the public health in Madras has been deteriorating, and not improving. The 10 years' ratios in the last column are exclusive of the enormous losses of the famine year, but they bear marks of the famine nevertheless, as these showed themselves in subsequent years. There is no such difficulty in comparing the years 1883 and 1884, and the conclusion is inevitable that the sanitary authorities in Madras have not as yet been able to make any impression on the epidemic susceptibility of the population. After many years of work and great outlay, their city has the most unfavourable health statistics of any large population group in India. This result could only have happened from some mistake in comprehending the nature of the problems to be dealt with, or in the methods employed. It may be safely said that, for a seaside city in India, were the death-rate reduced to half the present rate it would still be too high.

16. High as the present rate is, it differs in different groups of villages which go to make up the city. The lowest death-rate was 28·9 per 1,000 in four villages having a population of 19,010. In

another group of eight villages, with 66,655 inhabitants, the rate was 40·8 per 1,000. In another group of three villages the death-rate was 45·7 per 1,000, over 77,497 people. In other three villages, with 52,443 people, the death-rate was 47·1. In five villages, the population of which was 71,095, the rate was 50·4. In another group of four villages, the rate was 52·2 per 1,000, among 63,344 people. Another group of 37,940 people in six villages yielded a death-rate of 53·7, and another of 10,793 people in three villages had the enormous rate of 55·6 per 1,000.

17. With these facts before us, are we wrong in asking what would be the death-rates if there was no municipal sanitary administration at all, and also where is the proof that any efficient sanitary work has been done hitherto? The facts are so striking and so unlike any similar facts which have been presented by sanitary experience anywhere else, that, with the information before us that Madras has had its water-supply largely improved, and also an extensive cleansing system in operation for years, we must either consider the registration of deaths to be altogether untrustworthy, or that the past public health work has not been based on the true principles of prevention of disease.

18. With the statistical facts before us, it seems scarcely necessary to discuss the statements in the Report about the year's sanitary works, or to return to past controversies on their nature. It will perhaps be better simply to start from the fundamental facts already stated, which show that Madras is perhaps the most unhealthy city in India, and that its great death-rate is made up chiefly of epidemic diseases, which carried off 11,743 of its inhabitants out of a total loss of 20,123 by death. All the year's deaths except 8,380 were due to these diseases.

19. Now, all sanitary procedure which is intended to diminish or abolish liability to any class of diseases must be based on acquired knowledge of their causes, which comes by careful observation and experience. The causes differ according to locality and climate, and according to the manner in which locality is dealt with by the population covering it. Epidemic diseases may appear on mountain ranges or on seaside levels. In either case there must be local causes, but it does not follow that the causes should be the same. India presents examples of both classes of cases, as well as of intermediate ones, and it is one of the commonplaces of sanitary experience that, wherever there is stagnant subsoil water, so that the water table rises near the surface, there epidemics find their victims. It does not matter what other causes may be dealt with. This is the fundamental cause wherever it is present, and it can be added to almost indefinitely by filth being washed into the subsoil by rain or by foul drainage.

20. There is a report of 19 folio pages appended to the Municipal Report, and signed by the Officer of Health, but it throws no light on the local disease causes of Madras during 1884. It scarcely alludes to them, and it concerns itself more with the births and deaths, and what may be called the medical aspect of the facts, than with their causes.

21. Many years ago there was at least one municipal officer who told us what he had seen and learned on this all-important subject, but his facts and conclusions were subsequently denied by others. A year or two ago we inserted a statement showing the condition of the dwellings and compounds of the humbler classes. We adopted it as an instalment towards further knowledge, which was never supplied.

22. The most instructive sanitary fact in the present Report relates to the old controverted question of subsoil water level. Sewers have been laid in connexion with certain drainage operations, and the condition of the subsoil is thus stated:—"This portion of the sewer, from first to last, has "given a great deal of trouble. The soil met with was dark, black, and slushy mud, which "extended from 11 to 16 feet below ground level, while the foundation of the sewer was at the "depth of 13 feet." We know not how far this experience represents the condition of subsoil under the villages, but it seems to be matter for inquiry.

Alongside this statement regarding the subsoil of Madras may be quoted from the Report the following statement from the Executive Engineer of Calcutta, who writes:—"The brick sewers are "built with the very best hard burnt bricks and by hydraulic mortar. The pipe sewers are laid "in concrete, and jointed with a mixture of blue clay and Portland cement. Although the sewers "were not designed specially for that purpose, it is an undoubted fact that the level of the subsoil "water has been very considerably reduced all over the town. The subsoil water gets into the "sewers by an insensible percolation through the walls and joints of the sewers, and the walls of "the numerous manholes and lamp-holes. The proof of it lies,—(1) in the every-day fact that much "more fluid is drawn out of the sewers at the drainage pumping station than is supplied through "the waterworks; (2) in the evidence as to the drier condition of the ground floors of houses than "was formerly the case."

To this statement of the Calcutta Executive Engineer, we may add the following facts from our Memorandum on the Calcutta Report for 1882-83:—Referring to the work done by the sewage pumping engines, we stated that "during a period of 15 months, up to 31st March 1883, there were "raised on an average daily 15,514,836 gallons of sewage to a height of 8·78 feet to be discharged "into the outfall. Now it appears that the total daily water supply, filtered and unfiltered, "amounted at the same time to 9,663,301, hence making no allowance for evaporation, which, "however is an important exit for water, the amount of sewage raised and discharged by pumping "exceeded the total water-supply by 5,851,535 gallons, and to this extent the sewage system of "Calcutta afforded daily relief to the low water-logged site it is built on." Where sewage is pumped a large proportion of subsoil water enters the sewers and is pumped also. This must be beneficial, and should be extended.

23. Indeed, sewer systems may be, and have sometimes been, so constructed as to afford free ingress of subsoil water to the sewer, while the risk of escaping sewage has been provided against. Where the subsoil is wet and has been built over, special drains may be laid as deep as practicable and the water removed by pumping. Sewers in wet subsoils, if water enters to a moderate extent, will work better in a tropical climate than a dry sewer in a dry subsoil. Centrifugal pumps will raise large volumes of water 10 or 15 feet at a very small cost.

So far as this subsoil water question is concerned, Madras supplies one of the best illustrations of its disastrous effects on the public health, while Calcutta has shown what the remedy is, and how to apply it.

We my further contrast the death-rates of the two cities as follows:—

	Death-rates per 1,000.	
	Epidemic Diseases.	Total Deaths.
Madras - - - - -	30	50
Calcutta - - - - -	18·2	30·5

24. It seems unnecessary to pursue the subject further; our object, as already stated, is not controversial. We desire simply to call attention to the facts in order that their importance may be recognized and suitable improvements adopted by the Madras authorities, for the practical result of past experience is that the sanitary improvement of this great city has still to be undertaken.

22nd June 1886.

No. 13.

Memorandum of the Army Sanitary Commission on the Administration Report of Municipal Commissioner of Bombay for 1884–85.

1. In our Memorandum on the Report of 1883 we dealt chiefly with certain facts stated in the Report which had an important bearing on the susceptibility of the population of Bombay to epidemic outbursts of cholera and small-pox, and the general principles which in our view ought to be adopted in dealing with them. We have found nothing in the present Report to call for modification of what we then said on the subject, but in place of resuming the discussion it will, perhaps, be more advantageous to follow our usual course and to take up the sanitary history where we left it, and to see precisely what is the present state of the public health as shown by the statistics and by the various departmental reports included in the present volume.

2. The population element made use of in calculating locality ratios is that of the 1881 Census, which was 773,196. But we think there can be little doubt that the population of a great commercial and manufacturing city such as Bombay now is must have undergone considerable increase since the Census year, and hence that all the local ratios will be found too high for any purposes of comparison. This difficulty, which exists in all populations whose rate of increase year by year has not been determined, is one of the main difficulties in the way of estimating the sanitary condition of Bombay, and there is also reason to believe that the registration itself is incomplete. Our estimate will hence be based not only on the ratios but on the actual numbers on the register, so far as these can be depended upon.

3. *Births.*—The population of 1881 included,—

Males - - - - - -	464,763
Females - - - - - -	308,433
Total - - - -	773,196

In the review of the annual report by the Town Council the population is estimated at a total of 825,839, and the births, including still-born, at 16,148, or 17·72 per 1,000 on this number. Were this ratio correct it would show that only about half the births were registered. Taken on the population of 1881 the birth rate would be about 20·9 per 1,000, far below the true rate, and the conclusion is that the birth registration is quite useless for any purpose of comparison, and no more need be said about it.

4. *Deaths.*—Exclusive of still-born there were registered the following deaths:—

Males - - - -	11,757 = 25·29 per 1,000.
Females - - -	10,785 = 34·96 „
Total - -	22,542

The death-rate estimate on the assumed increase of population was 27·29 per 1,000; but on the Census population the death-rate would be a little over 29 per 1,000; nearer, but below the real death-rate if all the deaths were registered.

5. The deaths registered annually for the last eight years have stood as follows :—

Years.	Registered Deaths.
1877	33,511
1878	26,999
1879	22,527
1880	21,146
1881	21,856
1882	20,468
1883	23,530
1884	22,542

On the assumption that the registration errors have been tolerably constant during these eight years, we learn from the figures that subsequent to the famine year 1877 there had been a steady decline in the deaths, with an increase in 1883 not yet passed away.

6. The chief death causes during 1884 were as follows :—

Diseases.	Deaths.	Ratio per 1,000 of estimated Population.
Fevers	6,880	8·27
Respiratory diseases	3,744	4·53
Phthisis	3,091	3·74
Nervous system diseases	2,422	2·93
Diarrhœa	1,081	1·31
Dysentery	635	·77
Cholera	576	·70
Measles	456	·55
Small-pox	112	·13
All other causes	3,595	4·36
All causes	22,542	27·29

Of the registered mortality, 30·30 per cent was due to fevers. Another 30·30 per cent. was due to diseases of the chest, including consumption; and, classing together the diseases usually denominated as epidemic and endemic, we find that 43 per cent. of the year's deaths was yielded by them. But the more purely epidemic diseases, such as cholera and small-pox, the former of which caused 1,027 deaths in 1883, and the latter 1,461, were represented in 1884 by 576 deaths from cholera and 112 deaths from small-pox. This decline affords no proof that the local causes in 1884 were less intense in the latter than in the former year. The reduction was most probably due to less epidemic activity in 1884, and annual variation is, indeed, one of the characteristics of this class of diseases.

7. The endemic fevers of Bombay yielded an increase of 927 deaths over the fever death-rate of the preceding year.

8. These data include the sanitary elements for Bombay, but it is not sufficient to state them generally in this way. For practical purposes they must be localized, in order to be able to discover and remove their causes. This is shown in the next abstract :—

Localities.	Population, 1881.	Death-rates per 1,000 of Population, 1884.				
		Small-pox.	Cholera.	Fevers.	Phthisis, highest Ratios.	All Causes.
Colaba { Upper	9,867	—	—	2·44	—	33·13
Colaba { Middle and Lower	14,265	·07	·53	7·01	—	20·38

Worli	14,621	·40	1·09	10·46	—	26·94

These data are only for a single year, 1884, and would be liable to the usual annual variations if they were assumed as constants; but they nevertheless present facts that can scarcely be accepted as strictly accurate. It would appear as if further inquiry were necessary to introduce required corrections. Take, for example, the column representing the death ratio from phthisis. If the data were correct, we should have to rank consumption among the epidemics of Bombay. The year's ratios are apparently not accidental, because similar ratios are given in the Report for three successive years. It seems not unlikely that careful testing of cases would show that other chest diseases besides pulmonary consumption were included under the general designation of "phthisis," just as other diseases are included under the general head of "fevers." But if the ratios as they stand represent roughly the annual losses from phthisis in the most severely affected districts, they would have to be accepted as representing the existence of houses more crowded, of more unhealthy construction, and worse ventilation than could probably be found in any other city. This subject has for years been discussed by successive Officers of Health, and the necessity of town improvements for opening up the more densely-peopled parts has been fully admitted, and to some extent acted on. But the death statistics show as yet no improvement, and the Acting Officer of Health raises the question in the following passage of his special report:—"Plans for almost every description of insanitary buildings "are submitted. A not unfrequent plan is that of a chawl, three or four rooms deep, with, perhaps, "gullies only three or four feet wide on each side. The centre rooms of such a building have no "direct communication with the external air. They are dark unwholesome dens, into which the light "of day never penetrates, and which of necessity must breed disease and pestilence. This is only one "instance of the many unwholesome description of buildings being erected in Bombay."

He fully admits that the setting back of houses to widen streets is an "unmixed good" so far as the street is concerned, but in the absence of necessary Building Acts "by a large expenditure of "money on the one hand certain sanitary advantages are procured, which are in a measure counter-"balanced by defective legislation on the other."

10. He describes the proceedings as follows:—"A man intends to rebuild his house, in the rear of "which ten or twelve feet of open space had been left for ventilation. On submitting plans he is "perhaps called upon by the municipality to set back his house ten feet. What is the consequence? "He does not diminish the size of the house and still leave an open breathing space in the rear, of "ten feet; he literally sets back his house ten feet, and builds on the open space which had originally "been left for ventilation, thus shutting out light and air from the rear portion of the dwelling, and "rendering the back rooms dark unwholesome dens, into which light and pure air never enter." And he concludes, that "it is not only useless but detrimental to enlarge the breathing space of the "streets at the expense of the ventilation of the houses."

But on this view the Municipal Commissioner remarks that "there is no reason in Bombay, more "than elsewhere, that one improvement should be made at the expense of another."

It will be seen that the complaint of the Officer of Health is that nevertheless this is done. We may recall, in passing, that one of the most effectual measures for arresting epidemic diseases in Bombay used to be unroofing affected dwellings, a fact which proves the truth of the Officer of Health's view in another way.

11. The question raised by the preceding table is, whether the haphazard method of massing houses together described by the Officer of Health has been a possible factor in causing the enormous losses from phthisis which have taken place in the city; and the reply must be that just in proportion as original construction or subsequent rebuilding of dwellings has left the all-important requirement in a warm climate of free moving air not only around but inside dwellings unprovided for, will the usually crowded population of unhealthy localities suffer from phthisis and also from endemic diseases generally.

12. The practical result of this discussion is that the widening of streets in such a city as Bombay is of a very decided public advantage, but that it would be less costly and more effective at the same time to reconstruct the removed houses on strictly sanitary principles. Because, if this be not done at the time, it will, in all probability, have to be done afterwards at the public expense, while in the meantime the advantages to health which have been expected from widening the streets will have been only very partially realized, if realized at all.

13. A further examination of the preceding table shows that in nearly all the districts where phthisis is most fatal there are high death-rates from fever, which is a true endemic disease in

Bombay. A probable cause common to both diseases is very probably subsoil damp from defective drainage, for this is a well known cause, where it exists, both of fever and consumption, and it may be safely stated that stagnant, damp, impure air supplies a not unimportant factor in the entiology of both diseases in this city.

14. It will be learned from the table also that all the death-rates vary largely in the different localities. A similar distribution of ratios takes place in all large cities, and is adopted as an index of relative sanitary or insanitary condition, and as showing where outlay for works is required, and the probable nature and extent of them in each locality. In the present case the facts appear to show that there are circumscribed districts in Bombay were general sanitary improvements are greatly needed, and that these are probably subsoil drainage and opening up of closed neighbourhoods.

Mortality from cholera, although influenced by the same local conditions, is more closely connected with filth in air, earth, or water, and thus the table supports the conclusion that the healthiest town will always be that one where sanitary work in all its departments is most fully carried out.

So far as regards phthisis, we concur in the view expressed by the sanitary officer, who says, "unless we are enabled to deal with house sanitation in a more effectual manner than at present, I "fear there is little hope of reducing the death-rate from phthisis."

15. The Report contains no detailed account of the localities where epidemics prevailed in 1884, but in former Reports much useful information has been given about them.

16. As regards cholera, the Officer of Health has continued the details of the relation of this disease to the water-supply, which it may be well to give here simply as facts corrective of opinions still prevalent in certain parts of India that this disease is specially related to cholera-poisoned water.

The 576 cholera deaths which were registered in Bombay in 1884 were related to the quality of water used by the people as follows:—

	Attacked.	Died.
Vehar and Tulsi water drinkers	569	441
Well-water drinkers	89	71
Not known	76	61
Total	734	576

It thus appears that the population using the comparatively pure water conducted in pipes from the country reservoirs yielded 60 per cent. of the cholera attacks, and 77 per cent. of the deaths, while the population still using the bad well water containing foul subsoil drainage yielded about 12 per cent. of the attacks and 12·3 per cent. of the deaths. Although we have no means in either case of giving the ratios to the population using each class of waters, the facts are conclusive as against the specific action of well waters in cholera. They do not prove that bad water has no effect on cholera mortality, but rather the reverse. One result is obvious enough, and this is, that the Vehar water drinkers were affected by localising causes of cholera quite apart from the water-supply. This point is one of considerable importance in sanitary practice, because the facts clearly show that when the well-water drinkers are supplied by the Vehar and Tulsi water mains, which they will be before long, they will still suffer from cholera, and their case will be hopeless unless the real localising causes are dealt with, and what these are is quite well known.

17. We have so frequently discussed the disease history of Bombay that it is unnecessary to enter further on this subject at present, and it will perhaps be better to inquire generally into the present state of the sanitary works, beginning with the following remark in the Municipal Commissioner's Report. After stating that the more important disease causes are, it is hoped, about to be met by legislative remedies, he says, "In these cases the difficulty consists, not in detecting the blot, for that "is patent, but in providing a remedy which shall at once be effective and inflict the least possible "hardship. We have to deal with insanitary habits of very ancient standing, which the great body "of the population regard as perfectly innocent. In the carrying out of many of the most important "sanitary reforms we have to encounter opposition not merely from the ignorant, but from a large "population of the educated classes, and hasty or ill advised action would stimulate that opposition "to an extent which would render all action impossible." We must not forget, however, that similar language might have been used not long ago regarding the opposition to sanitary reforms in many English towns. It follows that the spread of information on the subject is of essential importance. This, to a large extent, ought to be effected by the ordinary municipal discussions and the press. But then it must never be forgotten that the most entire acquiescence of public opinion, say on the necessity of cleanliness, could not in a large city lead to any satisfactory result unless facilities for cleanliness were brought to the houses, and this is not domestic but municipal work.

18. The simple inspection of a cholera locality such as those described by Drs. Klein and Gibbes in their report to the India Office, and then raising the question who is to blame for this, the municipality or the people, ought to lead at once to a practical answer.

19. In such localities the measures required are mainly those which the people cannot apply, such as water-supply, drainage, and cleansing, and which are clearly municipal work. So far as relates to the sanitary state of the houses it would be in vain to look for improvement in this requisite of health so long as the external conditions remain such as have been described in the report referred to.

20. In his own Report the Municipal Commissioner states that house drainage connexions with the sewers are under trial in Kamathipura, and we have referred to this circumstance for the purpose of suggesting, if necessary, that all such trial works require continuous skilled inspection to avoid failure in some small and easily remediable matter which may involve the fate of the entire scheme.

We have introduced these remarks because they refer to matters of sanitary principle, but we are desirous that they should not be understood as implying that good work has not been done for improving the public health.

21. *Water-supply.*—On the contrary, a glance at the tables in the Report shows that, in drainage and water-supply especially, large advances have taken place in the course of the year. In times past there has no doubt been some miscalculation in the amount of water required, so that beginning with the Vehar reservoir, which was soon found to be insufficient for its object, another large reservoir at Tulsi has been constructed, and now it has been decided to add the Tansa scheme to the others, and it is to be hoped that the water-supply will in time be placed on a satisfactory footing, including filtration of the supply. The Bhundarwada waterworks for purifying and regulating the distribution of water had been completed, and had been found to be advantageous in regulating the supply and rendering it more uniform. But it has shown that 12 millions of gallons per diem will be required to meet the wants of the Vehar supplied districts, an amount in excess of what may be available. There was still considerable waste, but 250,000 gallons of waste per diem had been discovered and checked in the course of the year. The tank and filter works on Malabar hill appear also to be near completion.

22. We feel disposed to ask whether so large a number of bursts in water mains and consequent loss as shown in the following list are inevitable:—

Size of the Mains.	Number of Bursts.
48 inches	1
24 „	4
9 „	1
7 „	2
6 „	4
5 „	6
4 „	30
3 „	77
Total	125

23. In former Memoranda we gave the rainfall over the gathering area for Vehar, and the following table will show what has been the rainfall for both the areas at present yielding water:—

Years.	Rainfall, Inches.	
	Vehar.	Tulsi.
1880	72·42	93·76
1881	59·10	86·11
1882–83	54·63	74·22
1883–84	99·54	109·46

For the year 1884 itself the Vehar rainfall was 87·65 inches, and that over Tulsi was 94·84 inches. The facts show how unsafe it would be to depend on a single year's record for the amount of water available.

24. As regards distribution, the house connexions have been as follows:—

1880	12,494
1881	12,817
1882–83	13,244
1883–84	13,545
1884–85	13,909

The public water distribution is effected by,—

46 dipping wells.
56 drinking fountains.
24 stand pipes.
14 large ornamental fountains.
17 cattle troughs.

"All the dipping wells, drinking fountains, &c., were cleaned at short intervals." Better that there were no dipping wells to clean.

There were 715 private water meters and 102 Government meters in use.

25. *Drainage and sewerage.*—Perhaps the most important statement under this head is as follows:—"The discharge of the night-soil that used to be pumped into the harbour at Carnac "Bundar into the new main sewer at the same place is one of the chief features of the year's "administration."

The total quantity of sewage lifted during the year at the Love Grove pumping station was 415,914,598 cubic feet.

The pipe sewers of the first sanctioned portion of the drainage scheme have been completed, but the engineer states that "for want of connexions to conduct the sewage into the pipe sewers they are "doing scarcely any duty. Only in a few cases of new buildings, and of some old connexions (with "the old drains), which are irreparably bad, connexions have been made with the new pipe sewers "at the expense of the house owners."

26. Besides the general advance of the sewerage scheme, much good work for improving the surface drainage and regulating the overflow of storm water, and surface levelling, was done in the course of the year. But notwithstanding all that has been done we are still met by the fact that, while the current mortality from cholera has been greatly reduced, the people are still liable to outbursts of epidemics such as the one described in our Memorandum on last year's Report. Many conditions no doubt act together in leading to this result, but the one which all past experience shows to be the most fatal is defective cleanliness, and the evidence in our possession shows that this disease cause is present in all epidemic localities in the city. We have, in fact, to deal with a case, not of a village, but of a great city of some 800,000 inhabitants, the entire sewage of which has to be collected by hand labour and carried away, while this work must reach effectually not only the streets and better class of houses, but those closely packed, densely peopled localities where most of the people find house room.

27. *Cleansing.*—During the year 1884 there were employed in this work a daily average of 3,603 men and women, including those employed on surface work, and 540 carts, besides 127 used for collecting the night-soil. The staff collected and removed as an every day's average 389 tons of garbage and 295 tons of night-soil.

The total cost of this department of public health work was 83,955*l.*, of which 48,808*l.* was paid for by the Municipality, and the remainder was recouped to the Health Department apparently for work done. Any way, the larger sum shows the cost of this method of dealing with the question to the city. The amount included the cost of clearing out 197 miles of covered drains, which is a customary item in Bombay municipal work. Under any system efficient surface cleansing of all streets, lanes, compounds of houses, and other close localities is of course necessary, but it is not from ordinary street refuse that the danger comes. It is from the solid and liquid sewage of houses, and the filthy state of surroundings which this leads to, that the great losses of life from recurring epidemics arise.

28. It has been a long settled conclusion of sanitary science and experience that, in large cities at least, no attainable perfection in house cleansing can meet the every day dangers to which the people are exposed from disease emanations proceeding from their own excretions. But it has also been a long established result of sanitary engineering that the danger may be entirely avoided by applying natural laws in solving the problem. It can be effectually done by house drainage and water-supply, but in no other way. In a question such as this, where long established unhealthy popular habits have to be set aside, the real point requiring discussion is not whether the people prefer their bad habits to freedom from epidemics, but whether freedom from epidemics is or is not a public advantage. If it is, the discussion is ended, but, of course, in administrative matters of this kind, while the great leading truths must ever be kept in mind and their application in view, much wisdom is everywhere required in giving effect to them. It has happened in this country that loud objections against sanitary works for houses already executed have been at once destroyed by proposing to the objectors that the works should be removed, and things restored to their former state. Even in India trials of house drainage works have been conceded by their owners as a favour to the authority, while they have been at once adopted as soon as their great advantages had been experienced.

29. In conclusion, the Report under review shows that, in the important requirements of drainage and water-supply, advances have taken place in the course of the year, but there is ample evidence to show what a great amount of work in both directions requires to be done before the public health is out of danger, and of this fact perhaps the best evidence is that of the Municipal Commissioner himself, who "expresses a hope that the combination of a copious water-supply with efficient "drainage will lay the foundation of a permanent improvement in the public health of these "insanitary portions of the city; that in six years the Tansa scheme will have given the water-"supply, and that in less than that period the drainage will have been completed;" and he adds this important caution, which we have frequently given in past years,—"the admission of more water "necessitates the construction of more channels to remove it, in other words progress in drainage "operations." The two works in sanitary practice are inseparable. They are indeed one work, and their final object is to supply every person with water for domestic use, and to ensure continuous house cleansing and removal of sewage by gravitation to a distance. Any way this is the position of the works after about a quarter of a century of discussion and consideration of plans, and there are six years still to wait for their completion. In the meantime, all that can be done is to insist on the effective supervision of house construction and on great improvements in the arrangements for cleansing and keeping clean. The state of things revealed by Drs. Klein and Gibbes, and by the Officer of Health, ought no longer to be tolerated, and has not the Sanitary Commissioner for Bombay, who was for many years Officer of Health for the city, told us lately that Bombay is still an "Augean stable?"

25th June 1886

No. 14.

MEMORANDUM of the ARMY SANITARY COMMISSION on the following Papers :—

1. Sanitary Report of Madras Army, 1884, by Surgeon-General J. Irvine, M.D.
2. Remarks on the above by the Commander-in-Chief, Madras.
3. Report on Enteric Fever in the Madras European Army, 1884, by Surgeon-General J. Irvine, M.D.

These papers are separate references, but we shall include our remarks on them in one Memorandum. There is a separate paper by Surgeon-General Dr. Irvine, "Sanitary Report of British Troops in the Madras Command for 1884," which we shall also include, because all of them refer to the same subject.

1. The average strength of non-commissioned officers and men in the Madras European Army in 1884 was 10,812, as given by the Surgeon-General. But the average strength given by Dr. Stephen in his statistical tables differs slightly from the Surgeon-General's estimate; it is 10,785. The difference is so slight that we shall adopt that given in the Madras report. The year's facts will, therefore, stand as follows :—

		Ratio per 1,000.
Average strength	10,812	
Admissions to hospital	11,960	1,106·18
Total deaths	93	8·60
Invalids sent home	350	32·37
Average daily sick	639·49	57·5

Dr. Stephen's returns differ from the Surgeon-General's in giving 92 deaths instead of 93, and he states the average daily sick at 620. The two returns, therefore, differ from each other somewhat, but not to any material extent.

2. The really important points are given in this abstract which shows satisfactory progress in Army health.

	1874–83.	1884.
Admissions per 1,000	1,173·37	1,106·18
Deaths ditto	13·98	8·60
Invalids ditto	40·10	32·37

As we shall presently see, there are disease and death causes still in existence which ought to be abolished, but the results of the 1884 statistics show a very substantial gain to Army efficiency in all its elements.

3. As usually happens, the admission-rates vary considerably at different stations and in different years, but some of the stations have persistently high admission-rates.

Kamptee, for example, showed a ten years' average admission-rate of 1,460·27 per 1,000, and in 1884 the rate was 1,377·92 per 1,000. There must, of course, be some cause for this, and that it has something to do with locality appears to be shown by the fact that of the high rate of 1884 there was due to fevers 587·2 per 1,000, to dysentary and diarrhœa 55·3 per 1,000. Bangalore had a ten years' admission-rate of 1,145·81 per 1,000, and in 1884 of 1,006·48 per 1,000. In the same way Secunderabad, with a ten years' admission-rate of 1,145·81 per 1,000, yielded a rate in 1884 of 1,077·53. These cases have an important bearing on the question of Army efficiency, because of the number of troops stationed in the localities, although the admission-rates are not all due to local diseases.

4. The admission-rate for the whole Madras Army in 1884 was, as has been already stated 1,106·18 per 1,000; of this ratio 242·70 was due to venereal diseases, leaving for all other admissions a rate of 863·48 per 1,000. In the same way, of the Kamptee rate of 1,377·92, the venereal rate was 242 per 1,000; of the Bangalore rate 343·2 and of the Secunderabad rate 234·5 were due to syphilitic diseases.

5. Of mitigable or preventable fatal diseases, the most important were enteric fever, which yielded 129 admissions and 18 deaths, and cholera, for which 12 were admitted, and 10 of them died. The most fatal disease of the year was, however, hepatitis, to which 22 deaths were referred, and there were 9 deaths from apoplexy. There were 12 deaths out of hospital, to be deducted from the 93, which leaves 81 deaths, 59 of which were due to these four diseases.

6. The death causes of the year were as follow, including the above :—

Diseases.	Deaths.	Diseases.	Deaths.
Cholera	10	Hepatitis	22
Small-pox	1	Respiratory diseases	1
Enteric fever	18	Heart disease	1
Apoplexy	9	Phthisis pulmonalis	3
Delirium tremens	1	Wounds, &c.	1
Dysentery	4	All other causes	7
Diarrhœa	2	Deaths out of hospital	12

Taking the more important death-causes in order, we find that of the 10 cholera deaths 3 took place at Madras, 1 at St. Thomas' Mount, 1 at Poonamallee Depôt, 3 at Bangalore, 1 at Secunderadad, and 1 at Kamptee. Out of 12 cases of cholera in the Madras Army 10 died.

7. In connexion with these cholera deaths, it should be remembered that there were 75,476 deaths from the disease among the civil population at the same time. There was a severe epidemic in the Presidency, during which the Native Army had a cholera death-rate of 1·46 per 1,000, while the rate in the European Army was 0·92 per 1,000, both of which may be favourably contrasted with the rate of 2·7 per 1,000 which ruled among the civil population.

8. *Enteric Fever.*—As already has been stated, there were 18 deaths entered under this head in 1884, which was the mortality in 129 cases of enteric fever, and we shall first show the relation which this fever has borne in time past to the general fever history of the Madras Army. Assuming the strength in round numbers at 16,000, the admissions and deaths for 11 years have been as follow from all fevers:—

Fever Types.	1884.		Total in Ten Years 1874 to 1883.	
	Admitted.	Died.	Admitted.	Died.
Enteric fever	129	18	367	145
Simple continued fever	284	1	6,996	33
Febricula	626	—	4,607	
Remittent fever	104	—	907	28
Ague	762	—	14,594	1
Total	1,905	19	27,241	204

The average admission-rate from all fevers was for the ten years 253·33, and for 1884 it was 176·39 per 1,000. The corresponding death-rates were for ten years 1·88, and for 1884 1·76 per 1,000.

9. Of late years the nomenclature of this fever has been unsettled, on account of discussions on the subject of diagnosis of fever cases. This is well shown in the preceding table, and in the following abstract prepared by the Surgeon-General:—

Years.	Ratios per 1,000.		
	Admissions.	Deaths.	Deaths to treated.
1880	2·43	1·07	440·
1881	·86	·48	416·66
1882	4·34	2·12	479·47
1883	8·86	2·73	298·97
1884	11·94	1·67	134·38

This table shows that the diagnosis was unsettled, and it seems doubtful if all the cases entered under the head in 1884 were due to developed enteric fever. But it is also known that the mortality due to this fever does vary in particular years, and the Surgeon-General accepts the diagnosis. Hence, if we agree with his view on this point, we must adopt the consequence which follows from it, that of late years enteric fever has become a more prevalent disease in the Madras European Army.

10. We shall next show where the disease occurred, and we shall place together in the same table the admissions and deaths from cholera:—

Stations.	Enteric Fever.		Cholera.	
	Admissions.	Deaths.	Admissions.	Deaths.
St. Thomas' Mount	1	1	1	1
Cannanore	4	1	—	—
Malapuram	1	1	—	—
Bangalore	60	1	3	3
Bellary	3	1	—	—
Wellington	1	—	—	—
Secunderabad	39	10	2	1
Kamptee	25	8	1	1
Thyet Myo	1	—	—	—
Port Blair	3	—	—	—
Madras	—	1	3	3
Poonamalee	—	—	1	1

There was a case of enteric fever among troops on march, which recovered. On looking at the data in this table, it seems very doubtful if the 60 enteric fever cases at Bangalore, of which 59 recovered, were really due to this fever. One thing, however, must be admitted, and this is that there were 60 fever cases of so severe a character as to take rank with the most fatal of Indian fevers in the estimation of medical officers who treated them. But as the question is a very grave one, it may be suggested whether medical officers in their reports might not with advantage define what they mean by enteric fever, so as to avoid confusion so far as it may be possible to do so. If we accept the data thus far as they stand, we shall have the conclusion forced upon us that, out of 168 station fever cases, of which 18 died, 114 cases and 14 deaths took place at three stations, Bangalore, Secunderabad, and Kamptee, while at the same three stations there occurred seven cases and five deaths from cholera out of a total of 12 cases and 10 deaths in the Madras Army.

11. It is hence clear that in the present much improved sanitary state of the Madras Army there are nevertheless certain stations where there is preventable disease, and these are the stations where, in conformity with sanitary economics, a further reduction in the sick and death rates ought first to be sought.

12. The chief sanitary defects at these stations have been so long known that it seems almost unnecessary repetition to refer to them, but as they form part of the Surgeon-General's Report we may restate them. He says:—"Enteric fever has increased steadily during the last four years, "the increase being most marked in Bangalore, where the water-supply is always bad, and where it "was scanty as well as bad in 1884. It seems probable, therefore, that the quality of the water has "something to do with the spread of this disease. At Bangalore the barracks are all in good "sanitary condition, but some of them are, as stated in last year's Report, too close to densely "populated quarters which are under municipal authorities, and about the sanitation of which "frequent complaints are made."

The remark made by the Adjutant-General on the water question is very much the same as has presented itself year after year, namely, that "the question of improving the water-supply for the "troops at Bangalore, by abandoning the Ulsoor tank as a source of supply, is under consideration "of Government."

This tank was condemned a quarter of a century ago, and even then it had been shown for years to have been a probable disease cause.

13. In last year's Report on the Madras Army one medical officer referred to the probable influence of malaria proceeding from the drying up of the edges of the tank in summer on the amount of fever among the troops, and in the present Report the Surgeon-General tells us that the water-supply was "scanty as well as bad," and this fact implies concentration of all the water impurities under evaporation and absence of rain. We have thus to deal with a quite unsafe water-source which, as has been long known, receives its supply from a foul gathering surface, is liable to pollution from influx of foul drainage at Bangalore, its soluble impurities being liable to concentration by drying up, and the margins in all probability yielding unwholesome emanations at the same time. But, besides the dangers resulting from drying up of the tank, a fall of rain may increase the amount of filth in the water, for Surgeon-General Madden states that 22 cases of enteric fever, out of 30, admitted to the North Station Hospital occurred in July and August, when much impurity was washed by the monsoon rains into the Ulsoor tank, while organic decomposition was rapid and offensive in all low-lying localities.

14. We are glad to learn that the whole subject of the water-supply of troops has been under consideration, and that several projects have been brought forward, but we should be glad to learn within what time the Ulsoor tank and its surroundings are to be finally abolished.

15. But the Surgeon-General's brief remarks raise other very important questions. The civil population of Bangalore is that of a large city, and we are told in the present year's Report that "frequent complaints" have been made about the manner in which the municipal authorities perform "their sanitary duties in parts near the barracks."

16. In the present Report it is also remarked that "the discharge of the filth from the main "drain of Richmond town and Shoolay, within 200 yards of the old Lancers' riding school, had "probably something to do with the prevalence of the disease amongst the men of the 12th Lancers." As there are executive authorities on the spot, it would, of course, be advisable that they should do their work. But what if they neglect to do it? Are the troops to suffer on this account? And would it not be better to make such changes in the law or practice as would ensure that the part of this town near the barracks should be kept clean, and otherwise in good sanitary condition?

17. The following statement by the Surgeon-General regarding Secunderabad throws some light at least on febrile disease causes there. He says, "The main defects at Secunderabad are the want of "trees to check the force of the monsoon winds, and of surface drains to carry off the rain-water. At "present this water percolates into the soil and foundation of the buildings."

Where foundations are raised above the ground level with free perflation of air between the ground surface and the barrack floor, this defect of the subsoil is of less importance, but where the floors are laid without air spaces in malarial climates fever is a necessary result. But wet cultivation, with night-soil as a manure, is still carried on at no great distance from the barracks. As regards surface drainage, the Adjutant-General states that the cost of a complete system is prohibitive. But, in the meantime, it may be suggested whether raising the floors of the barracks in the way suggested would not remove much of the evil.

18. We are glad to learn from the Adjutant-General's letter that a scheme for the drainage of Secunderabad town is now under consideration. No complaint appears to have been made about the water-supply of troops at this station, so that the local causes of fever appear to be those connected with damp malaria producing subsoil under and around barracks, and probably emanations from wet sewage culture.

19. In this and indeed in all cases probably the effect of foul unhealthy bazaars and houses visited by the troops must not be overlooked. The subject is dwelt on by medical officers at stations, and the remedy is a long known one, namely, keeping the outskirts of stations free from disease causes.

20. The 15 cases and three deaths from enteric fever at Kamptee have led to the following expression of opinion as to the cause by the Surgeon-Major :—"In my opinion the *probable* cause of "the disease is the *latrines*. The men will not carry out the dry-earth system properly. I have "constantly noticed a fœcal smell in the neighbourhood of these buildings. All the cases of enteric fever were admitted to hospital during the rainy season, when there is a very damp and close con- "dition of the atmosphere, which produces rapid putrefaction and fermentation. The latrines are "cleared out morning and evening, and I think it very probable that a man visiting the latrines early "in the morning before the pans are cleared out would run the risk of contracting enteric fever." The large amount of enteric fever at Lucknow had previously been attributed to this state of the latrines as a probable cause by the Deputy Surgeon-General.

21. It is an old sanitary proverb that "all smell indicates disease and loss of money." Where badly managed latrines and filth are the causes of smell, the first part of the proverb will always hold good, and the second also if the profitable application of manure be neglected. We have here instances of two stations having latrines on what is called the dry-earth system, while it is not so. Sewage emanations are the result, and we may rest assured that these are active as disease causes beyond the limits of perceptible odour, and then we have enteric fever among the troops; and as to the remedy the Adjutant-General states that additional sweepers are required to go round and put dry earth in the pans after use by the men. We have had the subject so often before us that it seems scarcely necessary to restate the principles involved in the dry-earth system, but the practical remedy suggested by the Adjutant-General is the only one unless a suitable mechanism be provided in each seat. We may, however, repeat what has been said year after year since the report of the Royal Commission, that in such climates as exist in India there is no safety where there is sewage odour. This and not the occurrence of enteric fever cases is the real mark of danger, and whoever is charged with sanitary inspecting work should report on it again and again until the evil is dealt with.

22. The only other disease requiring notice is hepatitis, the mortality from which is differently stated in the reports and in Dr. Stephen's statistics. We have adopted the number of 22 deaths given in the statistics as the finally corrected one. Of these 22 deaths it is important to remark that 9 took place at Secunderabad; but we have no recent account of the causes.

23. The account given of the general sanitary condition of stations does not call for remark, as there seems every disposition to render the barracks and stations healthy, and indeed the low death and in efficiency rates of 1884 show how much good work has been done. There are, nevertheless, exceptional cases where sanitary improvement is needed, and we shall confine our recommendations to these.

1st. The proposed new water-supply for Bangalore should be pressed forward as quickly as possible, and authority should be brought to bear on the municipality to make them keep all that part of the town nearest the barracks in the best practicable sanitary condition.

2nd. It cannot be said that Secunderabad is as healthy as it ought to be. What appears to be required is the town drainage, regulation of wet culture, and in some way protecting ground floors from sub-soil damp. Probably partial subsoil drainage around the barracks would be of use, or raising the floors. We would further suggest that some account of the reasons why so many men die there of liver disease should be forthcoming. Tree planting, if carried out so as not to interfere with ventilation, would, no doubt, be an advantage.

3rd. As regards the latrine details at Kamptee, the remedy is obvious, but we must say that neither at Kamptee nor anywhere else ought such a state of latrine accommodation to be permitted.

8th June 1886.

No. 15.

Memorandum of the Army Sanitary Commission on the Medical History of the European Troops in the Bombay Command for 1884.

During the trooping season 1884–85 there were eleven outward voyages made by the usual transports. The first arrived at Bombay was that of the "Malabar" on the 10th October 1884; the latest, the "Jumna," arrived on 8th April 1885. In the course of the season there were landed at Bombay 639 officers, 126 ladies, and 134 children. Of troops in health there were 11,876 men, 402 women, and 553 children, besides 32 female servants, and there were also 20 horses,

2. In the course of these eleven voyages there were 906 admissions to hospital and 5 deaths. Among the admissions were included 237 cases of primary syphilis, 15 of secondary syphilis, 181 of gonorrhœa, and 15 cases of its sequelæ, making in all 548 from venereal diseases, or 60 per cent. of the admissions from all causes. There were 68 cases of itch, and 25 cases of pneumonia. The 5 deaths were due to rheumatism, sunstroke, heart disease, pneumonia, and injury. There were 15 admissions among officers, including a dislocation from a fall down a hatchway. From among the 402 women there were 35 admissions, and one death from congestive measles. The 553 children yielded 47 admissions and 3 deaths from convulsions, tabes mesenterica, and debility.

3. The sanitary state of the vessels was reported as "very satisfactory." This opinion appears to have been fully sustained by the results of the voyages, except in those cases with which the ships had nothing to do, namely, the venereal and itch cases, which are as great a trouble as ever, and are apparently without remedy. This matter, however, belongs to the administrative rather than to the sanitary department.

4. It is satisfactory to see that out of 639 officers and 11,876 men, 419 officers and 7,879 men arrived at Bombay before the end of the cold season.

5. The return voyages with invalids and time-expired men were effected by 12 troopship voyages and one hired transport. The earliest voyage commenced at Bombay on 28th August 1884, and the latest ship left Bombay on 16th April 1885. During the intervening period there left Bombay for England 428 officers, 162 ladies, and 204 children. Of troops in health there were 6,580 men, 343 women, and 763 children. Of invalids there were 1,407 men, 144 women, and 327 children. There were 62 insanes, 113 convicts and bad characters, and 21 horses. Assuming the duration of the home voyages at one month, 744 invalids, or about half the number, would arrive in England during spring and early summer.

6. *European Army of Bombay.*—We shall next discuss the year's sanitary history of troops at Bombay stations, but there are certain points connected with it which require to be kept in view in order to avoid the formation of erroneous estimates regarding the health of stations, and the steps necessary to be taken for their improvement. Of late years there has been a gradual advance in sanitary work, and a consequent reduction in the death-rates at the older stations, and it appears reasonable that this part of the question should be kept distinct from the effect on health of field service, or of the occupation of stations beyond the influence of improvements already effected. Although in the present report the health statistics of the Bombay Army are dealt with as a whole, the Surgeon-General has very properly discussed certain increments in disease and death-rates during 1884, with reference to special local and climatic conditions at the comparatively new station of Quetta, which furnished them; and we propose to follow the same course, and to deal with Quetta by itself, because it is quite evident from the facts that it would lead to false conclusions if the Quetta death-rate were apparently diminished by distributing its excesses over the improved stations, while at the same time the improvements required at the station would lose their support unless their necessity was shown by the facts.

7. The average annual strength of troops in the Bombay Command (including Quetta) during the year 1884 was 10,794 non-commissioned officers and men, and among these the causes of inefficiency were as follows:—

	Numbers.		Ratio per 1,000.
Admissions - - -	15,178	=	1,415·3
Deaths - - -	204	=	19·02
Constantly sick - - -	694	=	64·70
Invalided for discharge - -	113	=	34·52
Invalided for change - - -	225		

The death-rate of 1884 was 8·65 per 1,000 higher than the rate of 1883, and it exceeded the previous five years' average, which included field service deaths, by 2·43 per 1,000. The admission-rate was, however, 284·6 per 1,000 under the five years' average. The constantly sick was 1·07 per 1,000, and the invaliding 15·58 under the same average. It follows that the great increase in mortality was due to an outbreak of fatal disease somewhere, and we have next to see where this took place, and, as far as possible, to arrive at its causes.

8. We shall first inquire what were the inefficiency rates at the stations in Bombay, apart from the rates already stated which include those for the whole command.

The following are the data, exclusive of Quetta circle and of troops on march, and are those due to the Presidency, Sind, Poona, and Mhow circles, and to the sanitaria:—

Average strength - -	9,074	
Admissions - - -	12,498 = 1377 per 1,000.	
Deaths - - - -	102 = 11·2	„ „

9. These figures include the sanitary data for the Presidency stations properly so called, and we shall next contrast with them the facts regarding Quetta, which are as follows:—

Strength - - - -	1,075	
Admissions - - -	2,151 = 2,000 per 1,000.	
Deaths - - - -	41 = 38·14	„ „

The admission-rate at Quetta was thus about a third greater, and the death-rate about 3½ times greater, than the rates at the older Bombay stations.

10. But the high average death-rate for the whole Command included another element, which is thus described by the Surgeon-General :—"Quetta is the only station in the district in which British "soldiers are quartered, and ordinarily the marches of regiments and battalions to and from Sibi "do not call for remark. Last December was, however, made memorable by a virulent outbreak of "cholera in the 98th Regiment, while quitting the Bolan *en route* to India. The visitation was "short, but very fatal." In the statistical abstract given by the Surgeon-General, the strength of the regiment is given at 577. Its admission-rate at 906·8 per 1,000, and there were 61 deaths, equal to a death-rate of 105·72 per 1,000.

11. In Dr. Stephen's tables the facts are stated as follows :—"Zhob valley expedition and "marching in Southern Afghanistan," and the losses are stated as 39 from cholera, one from enteric and one from intermittent, four from remittent, five from apoplexy, six from respiratory, one from heart disease, and one from some other cause. There were 58 deaths in all, or a death rate of 53·31 per 1,000. This enormous death-rate was incurred in four months. The 58th Regiment appears to have met a cholera epidemic and passed through it on its return to India. The facts appear to be sufficient to justify a separate consideration of the sanitary problem presented by Southern Afghanistan, which, as will be hereafter seen, includes elements differing materially from those presented by Bombay stations generally.

12. We shall next give the chief death causes during 1884, including those at Quetta and on march, as these are stated by Dr. Stephens :—

Diseases.	Admissions per 1,000.	Deaths.	
		Number.	Deaths per 1,000.
Cholera	6·3	52	4·85
Small-pox	·7	1	·09
Enteric fever	·9·1	22	2·05
Intermittent fever	419·7	1	·09
Remittent fever	84·7	43	2·05
Continued fever		2	
Apoplexy, &c.	4·0	16	1·49
Delirium tremens	—	1	·09
Dysentery	26·5	11	1·03
Diarrhœa	53·2	2	·18
Hepatitis	18·9	11	1·03
Respiratory diseases	82·1	15	1·40
Heart disease	—	4	·37
Phthisis pulmonalis	8·1	8	·75
Violent deaths, wounds, &c.	14·6	24	2·24
All other causes	192·1	18	1·68

This abstract includes 208 deaths (or four more than the Surgeon-General's table) of which three deaths appear to have been suicides.

13. We shall next give a brief account of the chief death causes, beginning with cholera. As this abstract shows, there were 52 deaths from this disease; of these, 39 took place among troops on march in Southern Afghanistan, three among troops on march in Bombay Presidency, four at *Deolali* depôt, one at Poona, three at Mhow, one at Nusseerabad, and one at Neemuch. There was no death from cholera at Quetta. The mortality at Bombay stations was only ten; but of these four took place at Deolali depôt, which appears to require looking after, as this is by no means the first experience of the kind. But the cholera epidemic of the year fell on marching regiments, which yielded above four-fifths of the year's mortality.

14. *Enteric Fever.*—The next abstract shows the distribution of this fever in 1884 :—

Stations.	Cases.	Deaths.
Colaba	4	—
Belgaum	4	1
Poona	4	1
Ahmednagar	10	—
Mhow	5	2
Nasirabad	4	1
Neemuch	1	—
Baroda	5	1
Deesa	3	2
Karachi	28	3
Quetta	30	10
Zhob field force	1	—
On march	2	1
Total	98	22

15 The first question raised by these figures is the nature of the cases classed as enteric fever.

It may be admitted that the 22 fatal cases were of enteric fever because of post-mortem diagnosis, but it seems scarcely likely that 10 cases should have occurred at Ahmednagar, all of which recovered. Again, the Karachi cases yielded about one death to nine attacks, while the Quetta cases had a death-rate of one in three. It may be admitted that all the cases were of so severe a character that Medical Officers felt justified in classing them in the way shown in the table; but it seems not unlikely, as stated as his opinion by the Surgeon-General, "that many of those cases were possibly "aggravated forms of continued or remittent fevers, which in their progress assumed typhoid "characters." This view raises again the old question of the nature and relations of enteric fever to common Indian fevers, as will be seen from the following remarks by the Surgeon-General:—"The "typhoid state is a condition which may arise in the course of any febrile disorder when the approach "of death is gradual, and the rise of temperature either excessive or long continued. The typhoid "state is, however, most frequent in typhus, enteric, and yellow fever, and pernicious malarial fevers, "and in such cases the tendency is often evident from the very beginning of the attack." This view would, of course, divest enteric fever of any specific character, and would refer it to the position of a state or aggravation of febrile diseases in which the fatal termination was due to inteslinal lesions usually considered as marking the presence peculiarly of the fever known in our nomenclature as "enteric fever."

16. Our chief interest in the question attaches itself to available means of mitigating or preventing enteric fever attacks, and it seems necessary to state that, without calling in question the passage of Indian fevers into fatal enteric fever, the evidence as it stands appears to us to shew that "enteric "fever" properly so called is the fatal fever of India, and hence we conclude that the discrepancies between the attacks and deaths in the preceding table have been mainly due to defective diagnosis, but, while saying this much, we fully admit the difficulties which arise from the great prevalence of severe forms of malarial fever at Indian stations.

17. The Surgeon-General's remarks are accompanied by opinions of Medical Officers conversant with this fever as it showed itself at different stations which may be noticed. One of these, which the Surgeon-General says "was presumably formulated after patient observation of those cases which "did occur at Quetta last year," is that the disease is a "fecal" fever, which may be due to the gross habits of feeding of British soldiers in unaccustomed climates, where abnormal chills may cause internal congestions and disturbance of the whole digestive functions, of which enteric fever is the result, rather than to external causes, such as drainage defects.

Another medical officer, late of Quetta district, states that, "were it not for the frequent distinctly "tertian, quartan, and other remissions, and the non-progressive rise of temperature (in some cases) "from day to day, we should deem it absolutely identical with European typhoid. It is strongly "modified by, if it be not perhaps connected with, malaria, in the relation of effect and cause." Neither of these views, however, alters the fact that the fatal cases at Quetta were of enteric fever. No questions are raised at the Bombay stations as to the nature of the fever which is accepted as being "enteric fever."

18. Taking the data of 1884 as they stand, the Surgeon-General states his own opinion in the following words:—"1st. There is a form of fever called enteric fever which is not that disease "*proper*, but which is due to malaria, and presents great difficulties in diagnosis from true enteric "fever. 2nd. We have pure enteric fever, which I believe might almost invariably be traced to pre-"existing causes if our information were complete." As this view has a somewhat important bearing on sanitary work, it is necessary to state here that there is a very important difference, practically, between an ascertained fact and an unproved opinion, of which latter no account can be taken, especially where money has to be spent.

19. We shall next notice briefly the information in the Report on the presumed causes of enteric fever, and first as to the influence of age, which is shown year by year in a special table. It will, however, be sufficient for our purpose to give this in abstract, as follows:—

Ages.	Cases.	Deaths.
Under 25	79	18
Above 25	19	4
Total	98	22

So far as age is concerned in its relation to fever predisposition, this abstract shows the facts and their cause, while it suggests the remedy.

20. The effect of length of service is shown year by year in the same table, and the following results are abstracted from it:—

Length of Service.	Cases.	Deaths.
Under 3 years	79	17
Above 3 years	19	5
Total	98	22

There is nothing in either abstract that has not been long known, and together they affirmanew the principle that young ages and short service tend to keep up the death-rate from enteric fever, apart from all other predisposing causes.

21. But, as the next abstract shows, season has also a very material influence on the prevalence of fever :—

Months, 1882.	Enteric fever.	
	Admissions.	Deaths.
January	1	1
February	6	—
March	7	—
April	7	3
May	7	4
June	6	1
July	8	1
August	13	2
September	25	5
October	10	3
November	4	1
December	4	1
Total	98	22

It hence appears that the largest number of cases and deaths took place in the autumn months, but the absence of deaths in the first three months, with one solitary exception in January, confirms the view that cases of other fever types were included under enteric fever in these months, as well as during the autumn months, when 48 fever cases yielded only 10 deaths.

Where local causes are mentioned, they are of the following character.

22. *Karachi*.—At this station there were 28 cases and three deaths of enteric fever, and the Report states that "no cause for the prevalence of enteric fever can be found in the sanitary condition of the "barracks and their surroundings, for these are stated to be good." But it is admitted that the history of fever in regiments "bespeaks a grave sanitary defect somewhere." The Deputy Surgeon-General is of opinion that the disease is endemic at Karachi, and he advises that newly arrived regiments should never be placed in garrison at Karachi if it can be avoided. That there is a cause for all this does not admit of a doubt, but it does not follow that the cause is in the station itself. We have more than once called attention to the malaria, which in all probability proceeds from the back-water, and, in certain states of the wind this would easily reach the station and produce its characteristic effects there, and it was on this account chiefly that we advised formerly the removal of troops to Ghizri. There is a fact stated in the present Report which appears to confirm the view of this malaria being air-borne.

The barracks are in two stories, and out of 27 cases of fever 5 were received from the lower floors, and 22 from the upper floors of the blocks, clearly showing that the fever cause was more active in the upper floors, which could not be affected by the state of the subsoil; of course, without some local inquiry, this is only conjecture, but if there be air-borne malaria from the backwater it would be more likely to injure the men most exposed to its influence.

The practical result of this, as of previous discussions, is that it would be the cheapest way out of the difficulty to go to Ghizri, or at all events to give the proposal a fair trial.

23. Fever at *Ahmednagar* is attributed to impure water used for making ginger-beer, and also to impure bazaar milk, in which micro-organisms were found. Both causes come under local administration, and should be so dealt with.

24. At *Mhow* "no cause has been assigned for the outbreak by any Medical Officer." On the importation theory it is supposed that the Mhow cases were due to a gunner who had arrived at Mhow from Neemuch 21 days before his admission to hospital. But there was no enteric fever at Neemuch at the time to carry away, and the mere succession of cases at Mhow is assumed as evidence of cause and effect. The two first cases, both of which proved fatal, were admitted on the 21st and 29th April. The consecutive dates of the four cases which recovered were 6th June, 29th July, 15th August, and 25th October. There is no evidence whatever of causative relation between the cases, and it does not tend to increase our knowledge to plead the difficulties of inquiries. In practical sanitary work a fact is a fact or it is nothing.

25. At *Poona* there were six cases of enteric fever, of which one died. "No cause is assigned for the occurrence of the disease at this station."

The same remark is made regarding the three cases at *Deesa*.

26. One of the four *Nasirabad* cases is attributed to casual drinking of impure water, and others to a foul temple since destroyed.

No cause is assigned for the two cases at *Neemuch*.

A similar remark applies to the other local outbreaks.

We shall discuss the Quetta cases by themselves.

27. *Venereal diseases.*—The following admissions from these diseases were recorded in 1884:—

Primary syphilis	966 =	90·1 per 1,000.	
Secondary	204 =	19·0	„
Gonorrhœa	1,302 =	121·4	„
Sequelæ of ditto	289 =	26·9	„
	2,761 =	257·4	

As will be seen, the ratio of admissions under this head was high, and somewhat diminishes the hopes which of late years have been entertained regarding improvements by the agency of lock hospitals and police.

The admissions at Poona averaged 211 per 1,000, which is considered to be not an unfavourable result, due in part to what we long ago emphatically condemned, namely, that European soldiers were employed "to control prostitution."

So far as relates to the stations within the Presidency there is nothing further in the disease history of 1884 which calls for remark, and we shall next give a brief account of the sanitary condition and improvement in these stations during the year.

28. The first point of importance is the provision at present made for cases of infectious disease, especially among children landed at Colaba from the troopships. Properly speaking, there is none, but we learn that suitable provision will be made for this purpose in the new barrack project, but until this is completed there will be periodical need, and for meeting this a sufficiency of tent accommodation on healthy ground will be required; and it ought to be immediately available. A wooden hut or two would be better.

29. *Ghorpuri Barracks, Poona.*—The site of the new barracks was condemned before they were built. They had to be vacated on account of fever; after a time they were re-occupied, and at the end of June 1885 troops were removed again "owing to the excessive prevalence of "levers." We have never been informed how it was they came to be built in the face of the Report of the Sanitary Commissioner against the site.

30. At *Kirkee* it is proposed to collect the cook-house and wash-house water into stone tanks, whence it will be removed by hand, and the reason assigned for this proceeding is instructive. It is to avoid swampy ground "in the vicinity of the buildings from the overflowing of the present "receptacles, which are neither numerous enough nor of sufficient capacity." Of course swampy ground near or within a cantonment means fever.

In one barrack at this station another plan has been tried. So far as we understood it an area of ground sufficient to use up this drainage water is enclosed and prepared to a depth of 3½ feet. It is then traversed by porous pipes and filled up to the level with the usual soil. Water from cook-houses and wash-houses is conducted to the pipes by a drain, and thus is distributed to the soil, which is planted with Haryali grass, and so the drainage water is disposed of. The pit is 10 yards from the barrack, and is intended to be of sufficient size to dispose of the drainage water of the block. It had apparently answered for three months, but the rains had yet to try it. The case is one of drainage of separate buildings each by itself, and the disposal of the water for agriculture. A general system and one general application of the waste water would probably be both safer and cheaper, especially if the enclosed areas became swampy at the end of the rainy season. We must wait the result.

31. A necessary part of all buildings in which health and economy are deemed to be worth caring for is provision of gutters for removing roof-water. At Ahmednagar the Deputy Surgeon-General says that the Artillery barracks have gutters; but as regards the others, he very properly remarks that "the expense incurred in making improvements in this respect would be small compared with the "gain in health to the men and the diminished deterioration of buildings." The real wonder is why the barracks were left incomplete, and yet the local authorities say that it is not urgently required. If so, why were the Artillery barracks completed?

32. Here is another case at a sanatorium. The Medical Officer reports in regard to Purandhur, that "the surface drainage around the various buildings leaves much to be desired. There are "neither gutters under the eaves to receive the rain-water, nor (with one or two exceptions) are "there any drains round the buildings to carry it off, and to prevent it soaking in under the "building and appearing as moisture on the stone floors." The case of the female hospital is so bad from this cause that the executive engineer could suggest no remedy except that "hospital guard-room should be used as a hospital "for females during the monsoon." What can be said of this?

33. *Mhow.*—We are glad to learn that "the swamp near the Infantry barracks, noted in the "Report for 1883, has been efficiently drained," and that roof gutters and pipes have been put up at one barrack, to remove rain-water to a distance. One well has been deepened, permanently covered in, and the water is lifted by a force pump to an elevated tank and filtered for barrack use.

We have mentioned already that at Karachi the upper stories of barracks yielded more fever than the lower, showing that in all probability the fever cause was not in the subsoil so much as at a distance.

At Mhow, the Infantry, which is chiefly quartered in upper storied barracks, yield nearly four times as much "sickness" as the singled storied buildings. The exact diseases, and the proportion in upper storied rooms, are not given. But it is stated that the cases of fevers were "admitted "mainly from those buildings which the Sanitary Commissioner noted as being especially affected by "damp during the monsoon." And No. 4 Infantry barracks, in the neighbourhood of which there is defective surface and subsoil drainage, yielded nine fever cases. The relation of upper story rooms to fever requires elucidation, because it is possible, as has been already hinted, that the cause may be greater exposure to distant malaria sources.

34. *Nasirabad.*—The waste water from the ablution rooms is now passed into receptacles and carried away twice daily. New filter beds and a storage tank have been constructed in connexion with the Dánta water-supply. The death-rate at this station was augmented by a lightning stroke by which six deaths took place.

35. *Baroda.*—This unhealthy station, in which were well known sanitary defects in surface and subsoil drainage and in the state of the buildings, was, we are glad to say, completely vacated on the 1st October 1884. This, it will be seen, is the second group of barracks which it has been necessary to vacate in the course of the year because of obvious disease causes which, under a sound sanitary executive, ought not to have existed.

36. In the preceding paragraphs we have touched upon the chief points requiring notice in which general sanitary principles are involved, but there are a number of matters of detail in the stational reports which the authorities have every disposition to attend to as far as means are at their disposal.

37. Still limiting our remarks to the Presidency stations, there is evidence in the Report under review that the chief elements in the sanitary state of the stations are becoming better understood, and their importance to the health of troops duly appreciated. Much good work has been done with a corresponding saving of life and efficiency which is not shown in the statistics, because data are included which belong to the Command as a whole, and the data regarding Quetta and the troops on march in Southern Afghanistan have to be discussed for practical purposes as a separate problem, and we shall now see what light is thrown on the high death-rates there by the information in the present Report.

38. *Quetta.*—During the ten years 1874 to 1883 the average annual admissions at this station were 941·8 per 1,000, and the annual deaths 13·17 per 1,000, neither of them very high. But in 1884, out of a strength of 1,075, the admission-rate was 2,000·9 per 1,000, and the death rate 38·14 per 1,000, and there was not a single case or death from cholera.

The principal fatal diseases were the following:—

Enteric fever, 30 cases, 10 deaths.
Paroxysmal fever, 544 cases, 6 deaths.
Other fevers, 283 cases.
Tubercular diseases, 5 cases, 2 deaths.
Respiratory, 82 cases, 4 deaths.
Digestive, 523 cases, 11 deaths.

Of the last group 90 cases and 6 deaths were due to dysentery, 157 cases to diarrhœa, and 15 cases and 2 deaths to hepatitis, &c. The febrile group, together with those diseases of the digestive group that are usually associated with local and climatic causes, yield the data for the Quetta sanitary problem, at least for 1884, but we cannot overlook the fact that in the same region and in the space of four months 1,088 men on the march lost 39 men from cholera, so that in 1884 this epidemic, but for reasons unknown, might have fallen on Quetta also.

39. In dealing with the health conditions of Quetta, the first paragraph in the Medical Officer's report relates to the climate; the elements of which are contained in the following abstract from Mr. Blanford's Meteorology of India for the year 1883:—

Temperature and Rainfall.

Months.	Mean.	10 hours.	22 hours.	Mean of Maxima.	Mean daily range.	Mean of Minima.	Highest Maximum. Day.	Highest Maximum. °	Absolute Range.	Lowest Minimum. Day.	Lowest Minimum. °	Rainfall, 6 years' average.
January	37·6	49·5	44·2	67·8	27·5	30·3	4th	69·8	35·3	31st	12·8	0·94

* Mean of 27 days.
† Mean of 30 days.
‡ Mean of 26 days.
§ Mean of 22 days.

This table shows clearly what the character of the climate is, and its sensible qualities are described by the Medical Officer as follows:—"As to the climate ordinarily, that of Quetta is, owing

"to the 5,500 feet of elevation of the station, much milder during the summer than in Sind "or the Punjab, but in winter it is very cold, and in autumn the temperature variations are quick "and great."

40. The mean annual rainfall is only 8·24 inches, and above one half of the fall takes place in December, January, February, and March, that is, in the cold months. In this point the climate differs essentially from Indian climates. It is a climate of dry air, terrestrial radiation, and cold, and, if it can be said of any eastern climate that the elements usually productive of malaria are absent, this is the case at Quetta. The temperature variations are very remarkable. The table shows a difference of no less than 87·2° between the highest and lowest temperatures of the year, and the monthly ranges point to extreme day ranges also. For six months of the year the minimum temperatures are very low for the latitude, and the mean daily range is very considerable even during the hottest months, showing that at times the daily range must be great.

41. Absence of general malaria sources has not been attended by absence of malarial fever, for out of 876 admissions from the febrile group 544 were cases of paroxysmal fevers. But this is no new experience, for in past years there have been sudden outbreaks even among Native troops of ague disease.

42. When discussing this question formerly, we felt disposed to rank these fevers not as of primary malarial origin so much as being the result of resuscitated fever attacks originally contracted in the plains of India, and in the cases alluded to there was evidence to show that men had been stationed at Quetta without the modifications in clothing, shelter, &c., demanded by the peculiarities of the climate.

In clothing some improvement has taken place since then, and of clothing and bedding it is stated that "both appeared to be sufficient at all times, being lightened or increased as the seasons or "particular duties suggested," but then it is stated that "the uniform *clothing* was sufficient, and was "in winter supplemented by warm garments provided for men on night guards." The question naturally suggests itself here, What is meant by "uniform clothing?" Is it the uniform the men had previously worn at Indian stations, or is it a special Quetta uniform? If the former, then the meteorological table already given shows that it would not be sufficient to protect the men from the great difference between the climate of Quetta and the climates of India, apart altogether from the great temperature variations. We merely suggest the question for inquiry, because in the face of the disease statistics it requires an answer.

43. Next, as regards the accommodation for troops, we have the following statement:—"As to "shelter, it consisted in Quetta of newly built barracks of light structure, and of small, low-ceilinged, "dark, and dusty mud huts, plagued with flies in hot weather, and very difficult to warm in winter. "The hospital huts are scarcely better than the worst barrack huts in any respect."

44. These huts will be given up as soon as better accommodation is provided, but we may suggest that the class of barrack most suited for Indian stations on the hot sultry plains, little elevated above sea level, are not suited for climates such as that of Quetta, at an elevation of 5,500 feet above the sea, and we are told that in the new barracks already built "the fire-places are so placed and designed "that a proper radiation of heat fails to occur. The ventilation of the new barracks is rather "excessive, but will be made controllable, I believe."

45. The site of the station itself is not favourable, and requires to be fully taken into account in providing barrack accommodation. It is described as follows:—"The Quetta valley is overlaid by "dense clay, very stony where uncultivated, and the ground is formed into an endless series of "degrees of slope, all converging to the Shál Lora. So great are the inclines in the station itself "that to any one standing near a new barrack the old barracks and officers huts are much below the "line of sight. Hence rain-water runs off quickly, aided by an embankment on the east and broad "shallow channels dug for the purpose. The clay quickly dries, and percolation is apparently "small."

46. The remark suggested by this topographical statement is that every barrack room and sick ward and every quarter ought to be completely isolated from the slope above the site it occupies by a broad, open, clear, and well drained space.

Drinking water is provided from a guarded spring, and filtered before use.

We have made these remarks on the points in the Quetta Report as stated by the Medical Officers. But it is also stated that a special report had been made on the whole subject by the Sanitary Commissioners. This report is not among the papers. But there is sufficient in the Surgeon General's report to show not only the nature of this Quetta problem, but to prove at the same time that it requires separate consideration and separate treatment in some respects from that needed for Indian stations generally, and this is all the more important because there is a prospect of a large additional force being stationed in the country.

47. As regards the Bombay question generally, and apart from Quetta, the statistics show the result of good work done, but they also show the need of watchfulness, in order that the ground already gained may be kept, and the Report, as a whole, contains much useful sanitary information.

8th June 1886.

No. 16.

MEMORANDUM of the ARMY SANITARY COMMISSION on REPORTS on FAIRS and FESTIVALS held in the MADRAS PRESIDENCY during the latter months of 1883 and part of 1884 (Supplementary to No. 17, p. 251, Vol. xvii).

1. There are 22 registration districts in Madras Presidency from which returns of deaths from cholera were made in 1884. In 17 of these districts fairs and festivals were held in 1884. The facts regarding these are given in the Reports under review, but they also include 14 fairs held in 1883, which it is necessary to separate from those of the subsequent year in order to be able to compare the death-rates of the fairs of 1884 with the district rates of the same year.

2. Of the fairs held in 1883, one at Mayavaram, in Tanjore, had four deaths from cholera in November, and another at Tirupati, in North Arcot, held in October had six deaths.

3. Leaving these aside, the data in the Reports will stand as follows:—

Total number of festivals reported in the papers	147
Number held in 1883	14
Festivals held in 1884	133

4. Out of the total number of festivals deaths from cholera were returned from six, and non-fatal cases from one, so that seven were attacked; but, as has been just stated, two of the fairs at which deaths took place were held in 1883, and the fair where non-fatal cases were reported was also held in 1883. It follows that, of the 1884 festivals, four only yielded cholera deaths.

5. The total deaths reported for both years were 37, but as 10 of these deaths took place in 1883, we have to account for 27 deaths.

6. The data for 1884 thus stand as follows:—

Districts where fairs and festivals we held in 1884	17
Number of fairs and festivals	133
Number of these at which cholera appeared	4
Deaths at these four festivals	27

7. One important element in the question is unfortunately incomplete. We have not the numbers which attended the fairs in all cases. Only 77 out of 133 have made such returns, amounting in all to 1,114,200. If we assume the attendance at all the fairs to have been on a similar scale, we should have a population of about two millions as that which yielded the 27 deaths from cholera or about 0·013 per 1,000.

8. We can scarcely compare the nearly complete exemption of these temporary festivals with the year's death-rate for Madras Presidency, which was 2·7 per 1,000; but we can place side by side the district cholera deaths with the results of the festivals as follows:—

Districts.	Deaths from Cholera in 1884.	Number of Fairs in 1884.	Deaths from Cholera in 1884.	Names of Fairs attacked or where held.
Tanjore	23,671	13	11	Velanganny, in Tranquebar.
Malabar	337	8		
South Canara	None	2		
South Arcot	3,069	3	7	Chidambaram.
North Arcot	3,179	4		
Trichinopoly	4,517	1	4	Sriringham.
Bellary	1,068	4		
Salem	2,265	27		
Kistna	1,561	6		
Cuddapah	575	6		
Ganjam	172	3		
Godaveri	855	5		
Anantapur	239	4		
Madura	4,613	34		
Tinivelly	16,445	5	5	Srivilliputar.
Vizagapatam	14	2		
Chingleput	2,848	1		
Total in 17 districts	76,368	133	27	4

9. The statistical facts regarding the year's experience of these fairs may be summed up as follows:—The total deaths from cholera in Madras Presidency in 1884 were 75,476. Fairs and festivals were held in 17 districts out of 22. Deaths from cholera in these 17 districts were 70,368. In the course of the year 133 fairs and festivals were held, at which some two millions of people were present. Of these fairs cholera appeared at four, and the total mortality was 27 deaths, or in the approximate ratio of 0·013 per 1,000 of the total attendants.

10. The greatest mortality took place at one fair held in Tanjore district, where the epidemic was very severe, and the district death-rate 11·1 per 1,000, the highest of the year. In South Arcot, where one festival yielded seven deaths, the district death-rate was 4·4 per 1,000. The four deaths at Sriringham, in Trichinopoly, were part of a local epidemic which caused 20 deaths in the town, and the district death-rate was 3·7 per 1,000. Tinivelly death-rate was 9·6 per 1,000 for the district, and the five festival deaths were part of the epidemic. With the single exception of Madura district, which had a death-rate of 3·5 per 1·000, and no cholera at its 34 fairs, it may be stated that where the district death-rates were highest there was most risk from cholera at the fairs.

11. On one important branch of this inquiry the information is incomplete, namely, on the kind of sanitary measures which were adopted to preserve health during the fairs. In some cases, where these assemblages were held at or near small villages, no special precautions were taken. The villagers with their headmen attended to the work, which in such examples was perhaps the best way of having it done. In other cases nothing was done, but in 116 cases opinions on the sufficiency or insufficiency of the measures are expressed, often by Native officials. In 99 instances the precautions adopted are stated to have been "sufficient," and in 17 "insufficient." The principal means of preservation was cleansing sometimes by additional workers, and protection of water-sources. Several cases are given in which cholera was present in towns and villages where fairs were held without any of the pilgrims or other attendants having been attacked.

12. In the preceding table we have given the names of festivals where cholera appeared. At one of these, Velanganny, there were 11 deaths. There were about 15,000 people present, and the sanitary measures adopted are stated to have been "insufficient."

At Chidabaram, in South Arcot, where 5,000 people were assembled, the measures adopted were "unsatisfactory" and seven attendants died of cholera.

At Sriringham, in Trichinopoly, there were four deaths at the festival, and 20 in the town, not caused by it. The measures adopted were considered "satisfactory."

At Srivilliputur, in Tinivelly, there were assembled 15,000 people and 2,500 cattle. The only measure stated to have been adopted was providing latrines. At this fair there were five deaths from cholera, which, moreover, prevailed in the vicinity.

13. The following instance may be cited as one of notable exemption. Madura district had 4,613 deaths from cholera, and in this district Chittrai fair was held, at which there were present 150,000 people and 22,306 cattle. Sanitary measures stated to have been "sufficient" were adopted, and there was no cholera.

As a general rule, sanitary work was carried out at the fairs where there was no cholera.

14. The experience as a whole confirms that of former years, and shows that in the midst of severe district epidemics it is possible to obtain comparative immunity from cholera by precautions of a very simple and inexpensive kind. Cleanliness, prevention of nuisances and overcrowding, and keeping water-sources free from pollution, afford sufficient protection for people who have vacated their unwholesome villages and houses for a time. They are the same measures we have again and again advised for villages, and are stated in detail in our "Suggestions." Past experience justifies us in advising their continuance and improvement, and that the annual reports should enter more into detail, showing the actual sanitary condition of the localities, the numbers present, and the detailed precautions which were in force, as well as the results to health.
